ORIGINAL LECTURES.

GUNSHOT WOUND OF THE BODY.

A Clinical Lecture, Delivered at the Pennsylvania Hospital.

BY JOHN H. PACKARD, M.D.,
SURGEON TO THE HOSPITAL.

GENTLEMEN: On the evening of the 23d inst., there was brought into the hospital a woman who had just been shot by her husband. At my lecture the next day, as her condition was not such as to warrant her being brought before you, I gave you the details of her case.

She had received two shots from a revolver. One bullet had struck her on the right side of the thorax, two or three inches below the axilla, and had lodged beneath the skin, whence it was easily extracted by a slight incision by the resident surgeon. The other wound was in the left side, between the ninth and tenth ribs, a little in front of a vertical line passing through the axilla. A probe could be passed forward along the thoracic wall, in the track of the bullet, for about three inches; further than this the missile could not be followed.

I noted also a very small spot of ecchymosis on the surface of the right breast, an inch or more above and to the inner side of the nipple; but this did not then seem to have anything to do with either of the other wounds.

As nearly as could be ascertained, when the first shot was fired, the woman was facing her husband, and had her baby in her arms; the bullet, of the size known as thirty-two, struck her corset-bone, which dented it and destroyed its momentum, so that it merely penetrated the skin and lodged. On receiving this shot, she seems to have faced about away from the man, when he advanced toward her and fired again just as she stooped over to lay the child down. Thus, the first bullet struck her from in front, the second from her left side, ranging slightly upward and forward, as well as toward the median line of her body.

This woman's physique was singularly fine, and on admission there was very little shock. Her chief complaint was of pain and tenderness in the epigastrium, and in the right iliac region; she had no pain in the chest, although her breathing was somewhat embarrassed. At first sight it seemed to me probable that the second bullet might have entered the abdominal cavity and lodged there; and that the question arose whether it would not be best to follow it—to lay open the abdomen with the view of trying to repair any damage inflicted by the ball in its course, and of removing the ball if it were lodged where its presence would be likely to do further harm.

Such a procedure, which, a few years ago would have been regarded as utterly foolhardy, is among the recognized resources of modern surgery, and not a few instances are on record in which lives have been thus saved. Yet its gravity demands that it should be adopted only after careful weighing of the chances. I, therefore, sought the counsel of my colleagues, and abstained from disturbing the woman for examination until they should be present. Dr. Morton was the only one who could be reached, and he, very kindly, came at once.

On his arrival, we proceeded to examine the patient. There were no symptoms except such as have been already described; no tympanitic distention of the abdomen, and none of the general signs of internal hemorrhage. But when she sat up in bed, an examination of the chest showed dulness over the whole of its right side on percussion, while the respiratory sounds could scarcely be heard. This condition, coming on suddenly, could, under the circumstances, have but one meaning—there had been rapid hemorrhage into the pleural cavity. As there was no cough or expectoration of frothy blood, it was not probable that the lung had been wounded. We had no clew to the source of the bleeding, and could do nothing directly to check or control it. So grave and threatening a complication was of itself enough to forbid the idea of laparotomy.

We had here the statement that there were two bullets, and the examination of the woman's clothes bore it out; they showed on the right side the holes made by the first, coming from in front and from some distance; on the left, the holes at the side, with the stuff charred by the burning powder, showing that the shot was fired at very close range. The first bullet had been extracted, and had clearly not entered the pleural cavity. The second had evidently entered the abdominal cavity. What was the source of the hemorrhage into the pleura, and by which bullet was it caused? I was inclined to think, but wrongly, as it was afterward proved, that the first bullet had struck a rib, and detached from it a splinter, by which an intercostal artery had been wounded. It did not then occur to me that the second bullet could have gone into the thorax and caused the bleeding.

The woman was kept at perfect rest, under the influence of opium, with a large flaxseed poultice over the whole abdomen. Small quantities of liquid diet were ordered, and to allay her thirst she was given bits of ice to suck. The next day all her symptoms were aggravated, and there was decided evidence of failure of strength. Her countenance became pale, pinched, and anxious; her lips blue; her skin cool and bedewed with sweat; her pulse weak and rapid, and her breathing shallower and more oppressed. It seemed probable that there had been a continuous flow of blood into the pleural cavity; but she was too ill to allow of an examination of the chest merely in order to satisfy curiosity on this point. No distinct evidence of peritonitis was present. Death ensued about thirty-six hours after admission to the hospital.

At the autopsy, a most remarkable state of things was

discovered. The first bullet had simply, as supposed, penetrated the skin and lodged, doing no damage of any consequence. The second one had pursued a course as follows, which I will ask you to note carefully: Entering between the ninth and tenth left ribs, about an inch posterior to their junction with their cartilages, it ran along the wall, penetrated the diaphragm, and thus entered the abdominal cavity in a direction upward and inward; wounded the stomach near its lesser curvature and cardiac end; struck the liver two inches from its anterior border and one inch to the left of the suspensory ligament, across which it passed, ploughing the substance of the gland to the depth of half an inch and for a distance of three inches; pierced the diaphragm again, and cut the right mammary artery across; passing out at the fifth interspace, it then entered the mammary gland, reached the skin and made the small bruise referred to, dipped back again, and finally lodged under the skin about an inch from the point where the first bullet was found. The right pleural cavity contained about a pint and a half of fluid blood. In the peritoneal cavity there was no blood, but some undigested food, and the serous membrane was in a state of pronounced inflammation.

No disease of any organ was detected.

Now if the position of this woman at the time she received this shot be carefully considered—turning away and stooping over—it will be obvious that the course followed by the bullet, apparently so tortuous when described, was in fact almost a straight line. Only when the skin was reached and bruised was there a deflection, the tough skin offering more resistance than the areolar tissue and fat overlying the breast.

Very probably she was shrieking, and thus the diaphragm was strongly arched upward in expiration; this would not only slope the upper surface of the liver, but would bring the thinner part of the septum opposite the point at which the bullet left the gland.

I have great doubts whether, even if we had had a more accurate idea of this patient's position at the time of the shooting, we should have guessed at the course of the ball; for in the movement she was making, turning round and stooping over, there was a very complex change in the relations of the viscera to one another, as well as to the abdominal walls. Easy as this is to understand now, it must be remembered that we have the course of the ball as traced at the post-mortem examination to make it clear; it would not otherwise have suggested itself. And an accurate knowledge of the condition of things would have been of no avail in the matter of treatment.

The bullet had done all the damage it was going to do, and had lodged in a place where it was quite innocuous. Its removal was a matter of very small moment. A better illustration could hardly be afforded of the fallacy of the popular idea, that in cases of gunshot wound the finding and extraction of the ball must be at once effected, as of prime importance to the welfare of the patient.

Could anything have been gained in this case by surgical interference? Had the source of the hemorrhage into the pleura been known, there is no doubt the vessel could have been secured, but only by a procedure in itself difficult and grave. For mere ligation would not have answered; both ends of the divided artery must have been found and tied, or bleeding would have continued from the distal orifice, by reason of the free anastomosis existing with the epigastric. But, as before remarked, there was nothing to indicate at what portion of the thoracic wall a vessel had been wounded.

Had I opened the abdomen, I should have failed to find the bullet. The wound in the stomach could have been closed without difficulty, but, except by a very extensive division of the abdominal wall the thorough cleansing of the peritoneum could not have been effected, and inflammation of the serous membrane would otherwise have been inevitable. And although there had been no hemorrhage from the laceration of the liver, this lesion would scarcely have been amenable to any treatment.

In connection with this case, let me mention another which occurred in my ward last summer. A man, aged twenty-eight, was brought in one night, having been shot with a revolver an hour or two previously. The ball, fired at close range, had entered the left side of the abdomen, low down, and lodged. There was but little shock, and reaction soon ensued. The man was placed under the influence of opium, and ice-water was applied locally. He was stupid, but not unconscious—and was easily roused, so as to identify the man who had shot him. For three days his temperature remained at about 101.5°; then it went up to 103.5°. On the fourth day it was 104°, falling toward evening to 102.5°; then death ensued. At the autopsy it was found that the bullet had wounded the colon, and the ileum at two points, making five wounds; it had then penetrated the psoas magnus muscle, and lay between the transverse processes of the second and third lumbar vertebræ. Fecal matter had escaped into the peritoneal cavity and caused acute suppurative peritonitis.

It has always been a matter of regret to me that I did not, in this case, perform laparotomy, cleanse the serous membrane carefully, stitch up the wounds in the intestines, and thus give the patient the only chance for his life. One reason for this was that I did not see the patient until twelve hours or more had elapsed from the time of the shooting. Some difficulty was experienced in finding the ball, even at the post-mortem; but as it had lodged where it would have been comparatively harmless, its removal would not have been essential to success.

In still another case, recently admitted, a sailor had been shot in the abdomen about an hour previously, and was in a state of profound collapse, with a pale, cold surface, pinched face, and absence of pulse at the wrist. Here laparotomy was hopeless, and not to be thought of. The bullet was found to have wounded the spleen, causing fatal hemorrhage; it had then passed through the diaphragm, fractured a rib, and lodged under the skin.

Let me, in conclusion, offer some general remarks as to the operation of opening the abdomen in cases of gunshot wounds of this region.

It must be borne in mind that this procedure is itself of great gravity, and the patient's general condition must be fairly good to enable him to withstand the additional shock involved. The surgeon's prime object must be to do all that is possible to save life; but he must not overlook the fact that his course may be severely criticised, especially in cases which give rise to

medico-legal inquiry. Thus, as in the well-known Fisk case in New York, a few years since, it may be claimed that the treatment resorted to was the cause of death. Hence it is always advisable for the surgeon to have his own opinion fortified by the support of one or more consultants, especially in case of any departure from standard procedures, or from the rules laid down by recognized authorities.

There must always be reason to suppose that some definite object can be gained by opening the abdomen; such as the closure of wounds of the intestine, or the arrest of hemorrhage, or the cleansing of the peritoneum.

It must be a question to be decided in each case, whether the existing wound should be enlarged, or a new incision made in the linea alba. Generally I believe the latter to be best, as giving the freest and safest access to all wounded parts, and enabling the surgeon to assure himself that what is called by some the "peritoneal toilet" is thoroughly attended to. The median incision involves scarcely any bleeding, and what there is can be readily checked. If the incision is made in any other region, some vessels of importance are almost sure to be met with, and should be carefully secured as they spring.

Antiseptic precautions are eminently proper in these cases, although not indispensable.

Whatever is done must be done thoroughly. It would be absolutely useless to sew up all but one of the wounds of the intestine, or to tie all but one of the divided vessels, or to cleanse the peritoneum everywhere except in one recess.

I do not go into any detail as to the precise forms of suture to be used, the material to be employed for this purpose or for the tying of arteries, or the methods of dressing to be preferred. All these are matters about which different surgeons hold different opinions, and in which it is to be hoped that improvements will be made in the near future. The whole subject is one worthy of your careful study, and the more so that when you are called upon to act in such cases, there is no time for reading up, but your course must be promptly decided on and as promptly carried out.

ORIGINAL ARTICLES.

A CASE OF PENETRATING STAB WOUND OF THE ABDOMEN, WITH PROTRUSION AND WOUNDS OF THE INTESTINE.

BY HENRY W. BOONE, M.D.,
SURGEON TO ST. LUKE'S HOSPITAL, SHANGHAI, CHINA.

A. S., native of China, painter, aged twenty-one, single, admitted to the hospital December 27, at 11.15 P.M., about three hours after the receipt of his injury. He was stabbed in the abdomen with a large, sharp knife. The wound was two and three-quarters inches below the umbilicus, and one and a half inches to the left of the median line. A piece of small intestine fourteen inches long protruded from the wound. There were four wounds transverse to the long axis of the intestine; the mucous membrane was everted and protruding. The largest wound was one and a quarter inches long, the smallest half an inch. There was also a large ragged, contused, bloodshot surface on the gut near the mesenteric attachment. The mesenteric vessels were cut and bled freely in a good many places. This wound was one and three-quarters inches by one and a half inches, and was on both sides of the intestine near the mesenteric attachment. The protruded gut blocked up the wound of the abdominal wall, but it was not constricted enough to stop the bleeding from the wounded mesenteric vessels.

After consultation with my colleague, Dr. R. A. Jamieson, I decided to sew up the two clean cuts furthest from the large contused wound by the Czerny-Lembert suture. In order to save time, Dr. Jamieson sewed up one cut while I sewed up the other. We then passed strong double catgut ligatures through in two places, and tied the mesentery *en masse*, below the ragged wound which involved the vessels of the mesentery, then secured both sides of the gut and excised a piece three and a quarter inches in length, including the ragged part and the larger transverse cuts near it. The patient was much exhausted from the loss of blood which had occurred before he was brought to the hospital. As it was late at night and our supply of fine catgut was exhausted, we decided to secure the two ends of the gut in the wound and make an artificial anus. After the wound in the abdominal wall had been enlarged slightly by an upward incision, the two ends of the intestine were fastened to the circumference of the wound by deep sutures of strong braided silk which had been carbolized. These sutures went through the entire thickness of the abdominal wall including the peritoneum, and also through the serous and muscular coats of the intestine. The hands of the surgeons and assistants were thoroughly washed and carbolized, all instruments were dipped in a five per cent. carbolic solution, the sponges used were already prepared and lying in a five per cent. carbolic solution in a glass jar. The wound was irrigated with a warm two per cent. solution of carbolic acid and every precaution taken to keep it aseptic. The temperature of the room was kept up to 70°, and the patient had from time to time small doses of hot brandy and water. The solution of bichloride of mercury was not used, because the operator has been slightly poisoned by it on several occasions. After cleaning up the patient carefully, a large carbolized sponge was put over the wound and a lot of fresh tarry oakum put on.

Just as the wound was dressed, and before the bandage was put on, the patient vomited a large meal smelling strongly of liquor, which he admitted having taken. This food had not had time to pass from the stomach to the intestines. The intestines appeared to be empty. On raising the dressing the wound was found to be clean and not disturbed by the act of vomiting. Applied a binder, gave a hypodermatic of a quarter grain of morphia, and put him to bed with hot bottles, as he felt cold. The operation began at 11.45; it was completed and the man was put to bed at 2 P.M. At 2.45 P.M., he was sleeping soundly.

Dec. 28. 7.30 A.M., patient awake, is bright and cheerful, no pain, desires to eat. To have weak tea

to wet his lips with, nothing else. Morphia, one-quarter grain every four or five hours. 5 P.M., passed one pint of clear urine.

29th. Passed wind and some liquid by the anus. 9.30 A.M., removed the dressing, wound clean, healthy; powdered iodoform, oakum, and binder. 11.30 A.M., fecal matter flowed from wound and wet the dressings. 2.30 P.M., changed dressing. Soft yellowish-brown stool, three ounces, in dressing.

30th. Patient is a little tender to pressure over abdomen, but feels no pain.

31st. To take one ounce of beef tea every half hour. The native nurses could not be depended upon, and he would have taken food of his own choosing if I had not allowed him the beef tea. Abdomen slightly tender to touch, two inches larger than it was yesterday, tongue clean, moist, pulse soft. The highest temperature was $99\frac{3}{5}^{\circ}$ on the afternoon of the third day, highest respiration 22. He has a stool in dressing morning and evening when it is changed. The weather is very cold and raw. 9 P.M., temperature $101\frac{3}{5}^{\circ}$, cough and slight red streak in sputa, mild attack of pneumonia at bases of both lungs posteriorly; moved the patient, bedstead all, into a small room where we could keep him warmer. His skin is of a rather bad yellow color.

Jan. 1. Slept well, free from pain, slight cough, rusty and mucopurulent sputa, both in bowl; says he had bronchitis for two or three weeks before admission.

3d. An enormous round worm was found protruding from wound; passed nineteen worms at different times. Skin raw on left side of abdomen; zinc ointment.

4th. Bad night, looking very poorly; wound sunken and slightly ulcerated around the edges. Removed the stitches, as they were cutting into the skin. Although his pneumonia is clearing up, he is very feeble and worn out.

5th. Much better, he refused brandy and milk, complains that it makes him worse. Takes beef tea and rice gruel. He has no pain at all in abdomen.

8th. To have soup and fish. The patient has recovered from his pneumonia.

22d. Gave an enema of soap and water which returned unchanged.

27th. One month after the receipt of the injury, sat up in bed supported by a bed rest.

Feb. 9. The wound is healthy, has contracted and the patient is in excellent health. I tried to insert a rubber tube into both the upper and lower ends of the divided bowel. This plan was suggested by W. Mitchell Banks, surgeon to the Liverpool Royal Infirmary (*Med. Times and Gazette*, May 9, 1885, p. 603: Use of rubber tube in place of enterotome, to remove spur of intestine in artificial anus.) Found lower opening too small to receive the tube. Dilated lower opening with sponge tent, and inserted a rubber tube three-eighths of an inch in diameter, three inches into the upper, three and one-half inches into the lower end of the intestine and made it fast by a silk string. This thick, strong, elastic tube at once partly straightened itself, depressing the spur between the two ends of the bowel and becoming buried one-quarter of an inch below the surface of the wound.

11th. Some fecal matter passed by the anus.

12th. Removed small tube, and inserted rubber tube five-eighths inch in diameter, seven inches long.

14th. Enema with three ounces of castor oil, one good stool by the anus.

16th. One stool.

17th and *18th.* Slight diarrhœa. A very little fecal matter by the artificial opening. Has taken his food well all the time. Pulse and temperature good.

19th. Large stool by artificial anus.

23d. Doing well. An enema with two ounces of castor oil to insure stool by the rectum.

27th. He continues to pass his feces by the anus, little or none passing through the wound. He never has a stool by the anus unless the large enema with castor oil is given.

March 4. Removed the tube from the bowel to let patient try to pass feces naturally.

11th. Wound much better than it was one month ago when the rubber tube was first inserted, and it is more sunken. The tube was removed six days ago, he had one stool by the anus next day, since that time everything passes by the wound. As the enema is creating irritation and a slimy discharge, it was discontinued.

16th. On inserting the finger into the upper end of the bowel it goes in the full length into a large free intestinal cavity, and meets with no opposition. On inserting the finger into the lower end of the bowel it goes easily for two and a half inches, then enters a constriction which yields to pressure. The finger goes in as far as I can reach, but it is grasped with a peculiar motion, like a mouth sucking. It seems that the intestine is contracted at this point. A foreign body inserted here causes peristaltic action, but unless a large tube is passed through this place the feces all flow out through the artificial anus instead of going through the lower bowel. Attempts were then made to plug the artificial opening by a wad of cotton secured by adhesive plaster, but caused pain which the patient would not stand. He removed the plug.

17th. Painted all around artificial anus with collodion, to try to get the wound to close.

27th. Patient is well and gaining flesh. Still passes everything by the artificial opening. The wound contracted to a small hole which admits the forefinger. The patient and his friends desire a decisive answer as to his prospects. He was told that, as he was unwilling to submit to the very moderate pain caused by wearing a plug to close the artificial opening, the feces passed out through that orifice as the place where there was the least resistance. He was given the alternatives, to submit to the use of the plug, to undergo a resection of the divided ends of the bowel, or to return to his home. The dangers of the operation for a resection of the bowel were explained to him, and also the complete restoration which would ensue from a successful issue of the operation. After some days the patient and his friends determined that he should return home. They said that should he decide to submit to any further treatment he would return to the hospital.

30th. Discharged.

Remarks.—When the patient was admitted to the hospital he was greatly exhausted from loss of blood and chilled by exposure in his wet clothing to the freezing weather out of doors. My colleague and I came to the conclusion that we must excise a portion of the intestine as it was severed from its mesenteric attachments, and so greatly injured that it must necessarily become gangrenous if returned to the abdominal cavity. The man's condition was such that we deemed it necessary to complete the operation and get him to bed as soon as possible for fear of mortal collapse. We had no suitable needles or catgut at hand to join the two ends of the intestine with. Our assistants were Chinese, willing, but not very efficient, and we did not have all those appliances which a great hospital at home can place at the disposal of its surgeons.

On gently drawing down the ends of the intestine which protruded, it was found quite free from injury. I did not deem it necessary to perform a laparotomy and search for other visceral injuries. The wounded intestine and the extravasation of blood were outside of the abdominal cavity. It was specially an operation of emergency to stop bleeding in a patient with little vital power left; this prevented my choosing any plan of treatment which would have prolonged his stay upon the operating table.

With regard to the attempts at a final closure of the wound, there is no doubt in my mind that a persistent attempt to close the artificial anus by a well-fitting cotton pad secured by adhesive plaster would have been crowned with success. The peristaltic action of the bowel would have overcome the moderate resistance of the lower end of the intestine. The daily passage of fecal matter would have gradually accustomed the intestine to the resumption of its proper duties. Unfortunately, it is impossible to get a native nurse with the firmness needed to control an ignorant and wilful patient. No other nurses could be obtained, and for the want of power to carry out this simple and easily managed plan of treatment, I had to allow the patient to go home with an artificial anus.

The valuable assistance and advice of my friend and colleague, Dr. Jamieson, contributed very materially to the happy issue of the case.

PERNICIOUS ANÆMIA.

EXTREME REDUCTION OF THE NUMBER, WITH ALTERATIONS OF THE SIZE AND SHAPE, OF THE RED CORPUSCLES; RECOVERY.

BY FREDERICK P. HENRY, M.D.,

PROFESSOR OF CLINICAL MEDICINE AT THE PHILADELPHIA POLYCLINIC; PHYSICIAN TO THE EPISCOPAL HOSPITAL.

ON October 5, 1885, at the request of Dr. Morris J. Lewis, I examined the blood of a patient under his charge in the female medical ward of the Episcopal Hospital, and sent him the following report:

"Number of red corpuscles per cubic mm. 560,000. Percentage of corpuscles, as compared with the standard of health (5,000,000)—that is, the 'hæmic unit'—11.2 per cent. Hæmoglobin, 11 per cent. No white seen in the specimen examined. The corpuscles vary greatly in size and shape, many of them being much larger than normal. An undoubted case of pernicious anæmia."

On October 27 I examined the blood again, with the following result: Number of red corpuscles per c. mm., 840,000; white not increased; hæmic unit, 17; hæmoglobin, 12 per cent. The hæmoglobin had not increased in proportion to the increase of the corpuscles since the last examination.

On January 26, 1886, the patient was kindly sent to me by Dr. Henry M. Fisher, to whose care she had been transferred by Dr. Lewis, in the regular rotation of hospital service, shortly after my second examination. In a note which she brought with her, Dr. Fisher stated that he had quite recently examined the blood and found 3,431,250 red corpuscles per cubic millimetre.

The result of my examination was as follows: Number of red corpuscles, 3,670,000; hæmic unit, 73.5; color (hæmoglobin), 38 per cent; very few corpuscles above normal size; most of them smaller than normal; white very scanty; a few microcytes. The following notes were written at the time of this examination: "This case, which, at the first and second examinations, presented every symptom of pernicious anæmia, now resembles more one of chlorosis. Had I seen it to-day for the first time I would have unhesitatingly pronounced it a case of chlorosis, being led to such a diagnosis by the great diminution of the percentage of coloring matter as compared with that of the corpuscles. Taking 5,000,000 corpuscles as the healthy average per c. mm.—and this is high for a woman—the coloring matter in this case would represent 1,900,000 healthy corpuscles. The diminished percentage of hæmoglobin is now partly due to the diminished size of the corpuscles, as its former high percentage was due to their increased size. Is there a transition between idiopathic (pernicious) anæmia and chlorosis, and is this transition manifested in both directions? that is to say, is chlorosis sometimes the first stage of pernicious anæmia; and *vice versa*, Does a patient recovering from pernicious anæmia pass through a stage of chlorosis on his way toward recovery?"

Before attempting to discuss these points, I will append the clinical history of the case from notes furnished me by Dr. Fisher.

Anna D., æt. thirty-five years, English, domestic, married, sterile; was admitted September 18, 1885. The catamenia began at twelve, and were perfectly regular until June, 1885, when they ceased, and have not since returned. Her father died at the age of eighty-one; her mother of phthisis at fifty-five; one brother died of pneumonia at thirty; two sisters are still living. She was married at nineteen, and has never been pregnant. Has been in the country eleven years, and every summer has suffered from general debility and palpitation of the heart. Dates her present illness from April, 1884, and attributes it to the excitement and overexertion attendant upon a trip with a sick friend to Harrisburg. Her first symptoms were gradual loss of strength, with dyspnœa and palpitation on going up stairs; and sick stomach, with vomiting of watery fluid on rising in the morning. At present—time of admission—she complains of nothing but extreme weakness. Her hair has become quite gray during the last year, and her skin is of an icteric hue; while the conjunctiva is pearly-white, and the nails are whiter than the surrounding integument. Her bowels are moved twice a day, and the stools are natural in consistency and color. The tongue is pale red, without fur. The liver and spleen are of normal size, and no enlarged lymphatic glands can be found. There is no cough. The apex beat of heart is diffuse and slightly tremulous. It is felt in the sixth interspace, but is strongest in the fifth interspace, an inch and a half inside of the nipple. There

is a systolic murmur over the anterior surface, loudest over the pulmonary valves. There is a venous hum in the neck.

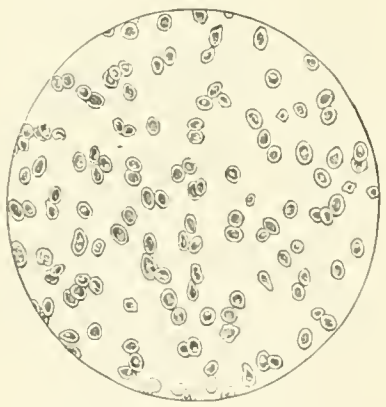
On admission, there was slight general œdema. The urine was free from casts, but contained pus corpuscles—three or four in every field—and a slight amount of albumen. The general intelligence is very good. Sleep is very poor.

The eyes were examined by Dr. B. Alexander Randall, one of the ophthalmic surgeons to the hospital, who made the following report: "Vessels pale; veins tortuous, particularly to the temporal side of left eye. No hemorrhagic spots, either new or old."

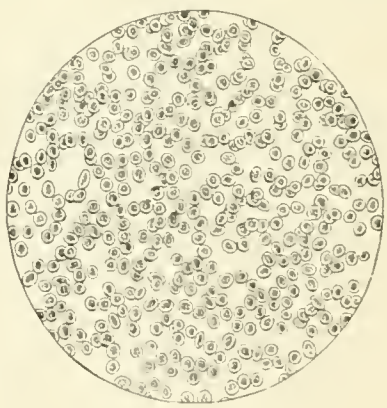
The treatment adopted was a Blaud's pill and Fowler's solution, gtt. v, thrice daily. This had to be stopped almost immediately on account of vomiting.

On November 4 liquor ferri dialysati, gtt. v ter in die, was prescribed. The dose was soon increased to twenty drops, thrice daily, and this treatment was continued until the patient's discharge from the hospital on Jauary 23d.

Although this woman's condition is, at the present date, by no means one of perfect health, yet she is able to go about and attend to light duties, speaks gratefully of her improvement, and intends to return shortly to England. These facts, however, would be very insufficient to warrant the published statement of her recovery. To prove that the case is one of recovery, it will be necessary first to consider what are the essential blood changes of pernicious anæmia; next, to show that they were well marked in the blood of this woman; and, finally, that they are no longer present.



Corpuscles of blood of pernicious anæmia.



Corpuscles of normal blood.

The cardinal features of the blood of pernicious anæmia are: great diminution in the number of the red corpuscles; no increase, or a slight relative increase, of the white corpuscles; increased size and altered shape of many of the red corpuscles; and, finally, a value in hæmoglobin of each red corpuscle equal to or exceeding the normal. This last is the most characteristic feature of the blood of pernicious anæmia, distinguishing it from all other forms, in which, without exception, the proportion of hæmoglobin is less than that of the red corpuscles.

In the case under consideration, the reduction in the number of the red corpuscles was extreme. A specimen of blood containing but 560,000 per cubic mm. is rarely encountered and never, I believe, in any disease but pernicious anæmia. They presented the well known alterations of size and shape, as figured in the accompanying cut; and, finally, the value of the corpuscles was normal, the hæmic unit being 11.2, and the proportion of hæmoglobin 11 per cent. The difference of 0.2 per cent. is infinitesimal. Notwithstanding the absence of retinal hemorrhage, so frequently met with in pernicious anæmia, there can be no question whatever concerning the diagnosis.

The question of recovery is more difficult and requires a little discussion. Recovery from a disease does not necessarily imply restoration to health. A patient with locomotor ataxia, Addison's disease, or phthisis, may recover completely from some intercurrent affection while the original disease persists. The fact that the primary may have given rise, directly or indirectly, to the secondary affection, has nothing to do with the question of recovery from the latter. In the case under consideration, a group of blood changes characteristic of but one disease—pernicious anæmia—is found by careful examination and, in the course of time, this is replaced by another set of conditions equally characteristic of another disease—chlorosis. A wonderful improvement in the patient's general condition has coincided with this radical blood change and, therefore, it is proper to speak of the case as one of recovery. The history of this patient demonstrates, so far as is possible on such evidence, that for years past she has been chlorotic.

The pernicious anæmia, from which I consider her to have recovered, was, therefore, an intercurrent affection, and the question propounded in the first part of this article, Is chlorosis sometimes the first stage of pernicious anæmia? may be considered answered in the affirmative. It merits, however, something more than a monosyllabic reply. Opinions are divided as to whether pernicious anæmia is due to the operation of a cause (unknown) *sui generis*, or to the prolonged operation of the ordinary causes of anæmia. The writer is of the opinion that the varied clinical history of the different cases on record furnishes most decided evidence in favor of the latter view. Anæmia once established tends to perpetuate itself in that species of vicious circle of which so many examples are furnished by pathology. Thus, to take an extreme example, the epileptiform con-

vulsions which immediately precede death from hemorrhage are due to cerebral ischæmia, and this very ischæmia is increased by the convulsions, for experiments have shown that the voluntary muscles contain a much greater amount of blood during contraction than while at rest. It is quite as essential to the blood-making organs as it is to the nerve centres that they be properly supplied with blood in order that they may act their important part toward maintaining the bodily health. Doubtless there are reserve powers and compensatory activities in each and all of the blood-making organs which may suffice to furnish a fair quality of blood under the most adverse circumstances. These powers, however, have their limit, and, once exhausted, the anæmia instead of continuing "simple," "functional," or "symptomatic," becomes "essential," "organic," or "pernicious."

The second question, Does a patient, recovering from pernicious anæmia, pass through a stage of chlorosis? is now to be considered. Nothing is more difficult in medical research than to obtain examples of any fact in the clinical history of a disease which has not before attracted particular attention. In addition to my own case, I know of but one other, reported by Laache,[1] in which, with restoration of the normal number of corpuscles, the proportion of coloring matter remained so much below normal as to warrant the designation of the condition as chlorotic. I believe that attention has only to be called to the facts of my own case in order to make general the observation that chlorosis is frequently the first stage of pernicious anæmia, and that a patient recovering from the latter disease frequently, perhaps invariably, passes through a stage in which, with a greatly increased, perhaps a normal, number of red corpuscles, the proportion of coloring matter is far inferior—that is, a stage of chlorosis.

FIFTY CASES OF LACERATED CERVIX TREATED BY SILKWORM GUT SUTURE AND IODOFORM.

By R. STANSBURY SUTTON, M.D.,
of Pittsburg.

Two weeks ago I completed a line of fifty lacerated cervix operations. These cases were all done in about twenty-four months. Each patient was prepared as usual, or as Emmet teaches. The instruments, sponges, and ligatures were scalded and used directly from the bath when sufficiently cool. The lips were well denuded, sound tissue being sought for always. They were carefully approximated and united with silkworm gut sutures, the ends left long. The cervix was then covered with a small teaspoonful of iodoform. The patient was put to bed, the catheter was not to be used unless the patient failed at the end of eight hours to pass water, and not again if it could be avoided. No douches were permitted until the sixth or, more generally, the seventh day, when a douche was given to clean the vagina preparatory to removing the sutures.

In forty nine of the cases the temperature never exceeded 100° F., and in many of them 99° F. In one some sepsis occurred and the temperature exceeded 100° F. All recovered; in one there remained for a short time a fistulous opening at the site of the upper stitch. In one the lower stitch cut out. Both were unilateral cases.

Silver wire and douches and catheter can give no better results, and this method of treatment is infinitely less annoying to the patients.

The large amount of iodoform has not given any trouble. Those who will follow me in this method will, I believe, find it an advantage over the method of silver sutures and frequent douches. They will get lower temperatures and these cases will require no skilled nurse.

Any ordinary attendant who will do only what she is told to do will answer as well as the best.

I will do fifty cases with silk and chemically pure powdered boracic acid. But better results than I have obtained in the fifty cases reported above can scarcely be expected.

419 Penn Avenue, June, 1886.

MEDICAL PROGRESS.

Massage as a Therapeutic Agent.—Dr William Murrell, in the *British Medical Journal* for May 15, 1886, discusses as follows the field of therapeutic usefulness of massage:

It is no easy matter to say in what class of diseases massage proves most useful. Unfortunately, its employment has been advocated in many cases for which it is essentially unsuited. Accurate diagnosis is of the utmost importance, and the sphere of usefulness of this remedy will, with increased experience, become more accurately defined. My best results have been in infantile paralysis; and it was in consequence of the success achieved in certain obstinate cases of this disease, that my attention, as has been elsewhere stated, was directed to the subject. Progress is often slow, but the ultimate results are most satisfactory. The nutrition of the parts is maintained until new cells in the spinal cord take on the functions of those which have undergone degeneration, or have been destroyed. Massage is, undoubtedly, of much value in many cases of obstinate neuralgia, and succeeds admirably in some forms of muscular pain, such, for example, as those described by the late Dr. Inman under the term "myalgia." There is a general consensus of opinion that it is well adapted to the treatment of chronic joint affections; and most of those I saw treated by von Mosengeil were such as would, in this country, be considered incurable, or would drift into the hands of "bone-setters." There are some diseases of internal organs in which it is, undoubtedly, useful. Not long ago a gentleman, aged sixty-eight, came to me complaining of shortness of breath, and increasing disinclination to take exercise. He had been in business, and had led a most active and energetic life. Three or four years ago he retired, and, from that time, experienced a gradual falling off in health. His appetite was poor, his bowels were obstinately confined, and he was nervous and anxious about himself. He was found to have a loud apex systolic murmur, and

[1] Die Anämie, p. 190, Case No. 9.

the heart's action was weak and irregular. I suggested massage, which was carried out systematically four days a week for a period of six weeks. He improved from the very first, and, before the conclusion of the course, was better than he had been for many months. His appetite returned; his hands and feet were warmer; the bowels became regular; he slept well at night; and his spirits improved in a most satisfactory manner. In other cases of obstinate constipation, especially in women, I have known massage of the abdomen do a great deal of good.

In a well-known group of symptoms from which women frequently suffer, massage is essentially useful. I recently saw a lady, aged forty-five, or thereabouts, a professional singer, who was laboring under the impression that she was going mad. She was so nervous that she was quite unable to accept an engagement, although she had been constantly before the public, and had hardly missed a night for twenty years. She told me that she felt she was not to be trusted, and that, if left alone, she would do herself or her children an injury. She was afraid to go near an open window, so great was the temptation to throw herself out; and she even begged that the knives might be removed from the table at dinner. These symptoms were greatly intensified after each monthly period, and she insisted that she was suffering from cancer, or some organic disease of the stomach or womb. She was restless at night, and would often get up in the early morning, and walk for hours, until thoroughly exhausted. She was given full doses of the bromides—a drachm, or more, four times a day—but with only temporary benefit. Massage was then tried; and it seemed, to use her own expression, to soothe her, and calm her, and make her forget her troubles. The case was a prolonged one, but now, at the expiration of three months, she is much better, and will soon be able to resume her professional duties. In several other cases of restlessness and inability to sleep, the same method of treatment has proved efficacious.

Dr. Graham, of New York, speaks highly of massage in the treatment of neurasthenia. He uses it for those "who, in spite of rest, change, and medication, have become chronic neurasthenics, the result of business reverses, overwork, worry, loss of relatives, disappointed hopes, or as a sequel of some affection that has existed in some part of the system, but which has been recovered from or has become of secondary importance." These symptoms may be somewhat ill-defined; but I have certainly found massage of the greatest use in what, for want of a better name, has been called "spinal nervous weakness," or "neurasthenia spinalis."

In the treatment of corpulence associated with constipation, massage is of much value. Some months ago I saw a lady, aged thirty-eight, who, as the result of much good living and little exercise, had become inordinately stout. She was very short of breath, and was disinclined for exertion of any kind. She had been fond of literary pursuits, but even those had lost their charm, and were irksome to her. She was extremely irritable, and a source of trouble and anxiety to her friends and relatives. Massage was prescribed, and in two months she lost a stone and a half in weight, and improved notably in other respects.

For many forms of menstrual disturbance, massage may be safely prescribed. I recently saw a young lady, aged nineteen, who suffered intensely at each monthly period, the pain being so severe that hypodermatic injections of morphine had to be resorted to. Massage of the abdomen and pelvis was prescribed, and from that time there was no return of the trouble. Cazeaux has reported several similar cases, in detail. In the convalescence from acute illnesses, this mode of treatment is a great help and comfort to the patient. There can be no doubt that massage is a very valuable therapeutic agent, and is likely to yield good results in many complaints other than those I have roughly indicated.

Paraldehyde as an Antidote to Strychnine.—Bókai finds from numerous experiments on frogs, that the absolute lethal dose of strychnine sulphate in these animals ($\frac{1}{60}$ to $\frac{1}{30}$ grain) is not fatal when they are previously stupefied by the administration of 1½ to 3 grains of paraldehyde. Rabbits, also, when previously stupefied by paraldehyde, will resist amounts of strychnine which exceed many fold the minimal fatal dose. Similar results have been observed in dogs.

Bókai proposes the administration of paraldehyde in acute strychnine poisoning in man, and states that in this case the dose would vary between 90 and 180 grains of the antidote. It should present certain advantages over chloroform and chloral hitherto used with good results in this condition, in that it exerts no deleterious action on the heart.—*Centralb. f. klin. Med.*, April 10, 1886.

Paralysis of the "Glottis Dilators" as the Initial Symptom of Tabes Dorsalis.—Prof. A. Weil, of Heidelberg, in the *Berl. klin. Wochenschrift*, for March 29, 1886, gives a full account of a case of tabes dorsalis, which set in with peculiar laryngeal symptoms. The patient is a man, æt. forty-nine, and a pilot on one of the large rivers of Germany. About a year before he consulted Prof. Weil he had passed through intense excitement, from the fact that his boat was in danger of colliding with another. He issued his commands in a very loud tone of voice, and immediately thereafter had an attack of extreme dyspnœa, which lasted about ten minutes with crowing respiration, etc. Eleven months later he had a second attack of the same sort. From that time the least exertion produced a loud snoring respiration. Laryngoscopic examination showed that the margins of the glottis were two to three mm. apart during expiration, but during inspiration there was nothing but a cleft-like opening left. Phonation was entirely normal. These symptoms differ from those of ordinary laryngeal crises in several particulars: 1. They are not distinctly paroxysmal; there is a *permanent morbid condition* which is aggravated by physical exertion or mental excitement. 2. There is no cough. In regard to the question whether these symptoms are due to paralysis of the *ab*ductor or spasm of the *ad*ductor muscles, the author is not prepared to give a definite answer, but he inclines to the view that there is paralysis of the dilator muscles. The author gives a list of published cases in which symptoms of this sort were observed. He refers very properly to the necessity of examining for tabes in all cases of sudden paralysis of the vocal cords.—*Journal of Nervous and Mental Disease*, May, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 3, 1886.

ARTERIO-VENOUS ANEURISM.

THE occurrence of an aneurismal communication between an artery and a vein has fortunately never been very common, and it is believed to be less common in recent times than it was formerly, because the practice of venesection has fallen into disuse. Of this we cannot be so sure. For, although a large proportion of the aneurisms spoken of by the ancients, of whom Galen was the first to speak distinctly, were probably of this character and caused by venesection, nevertheless a careful study of the best statistics shows that a great many of the recorded cases are to be attributed to other traumatisms, and that not a few have been spontaneous. Thus BRAMANN, in an elaborate paper read before the Fourteenth Congress of German Surgeons, which appears in the *Archiv für klin. Chirurgie*, Bd. xxxiii. Heft 1, has collected the reports of 159 cases, in only 56 of which was venesection the cause, while 52 were attributed to other sorts of incised wounds, 29 to gunshot wounds, 1 to a contused wound, 5 to contusions, 1 to abscess, 1 followed an amputation, 1 followed castration (in an ox), the cause is not stated in 4 cases, and 9 were spontaneous. So, also, Barwell, in the article on "Aneurism," in the *International Encyclopædia of Surgery*, mentions 42 cases of arterio-venous aneurism involving the aorta, in 35 of which the lesion was certainly within the thorax, and this although the first accessible report of an aneurism in this locality, refers to a case published by Syme so recently as 1831.

It is a curious fact that, in comparison with this large number of cases, Bramann's table contains only one case of arterio-venous aneurism of the aorta and iliac vein, and one of the common iliac vessels. On the other hand, it includes 13 cases in which the lesion was in the vessels of the head, 16 in which it involved the carotid artery and the jugular vein, 11 in which it involved the vessels of the axilla, 63 in which the brachial artery and vein were involved, 36 in which the vessels of the thigh were involved, 14 in which the popliteal vessels were involved, 2 in which the vessels of the foot were involved, 1 in which the retinal vessels were involved, and 1 in which the lesion was situated in the stump of the spermatic cord in a castrated ox. This review of the situations in which arterio venous aneurisms have been noted indicates that the abandonment of the practice of phlebotomy cannot be expected to lead to the disappearance of this lesion, and that it is still worth while to study its nature, prognosis, and treatment.

This has been so thoroughly done by Bramann, that his conclusions merit careful appreciation. As to the prognosis of arterio-venous aneurisms, his statistics do not support the common opinion that the form called aneurismal varix (in which there is a direct communication between the artery and the vein) has a favorable prognosis, and that the form called varicose aneurism (in which there is an intermediate sac) has a bad one. The latter opinion he shares, indeed; but he finds that, although it rarely threatens the life of the patient, the aneurismal varix tends to such serious interference with the function of the limbs as to make its prognosis essentially unfavorable. As to the treatment, Bramann does not find much encouragement for the employment of digital or other compression, except as a preparatory measure; he rejects distant ligation, but endorses the method of ligating the vessels immediately above and below the aneurism, and splitting open or excising the sac. The only contraindication to this procedure, he says, is very serious disease of the blood-vessels.

It is usual in the books to warn against including the vein in the ligature applied to an arterio-venous aneurism; but this is probably not so dangerous a procedure as might at first be supposed. It is certainly to be avoided, if possible, in the case of the larger venous trunks, while it is probably of little consequence where the smaller ones are concerned. Finally, what we have said in speaking of the method of Antyllus, as applied to other forms of aneurism, in THE MEDICAL NEWS for May 1, 1886, is true in this connection, namely, that thorough excision is not to be looked upon as involving, at the present time, the dangers to which patients were liable before surgeons were as careful and as skilful in avoiding septic disturbances as they now are. Nor is it to be forgotten that conscientiousness, anatomical knowledge, and manual dexterity are factors of success which cannot be made to appear in tables of statistics.

Almost simultaneously with the appearance of the paper of Bramann, another has been published by Pluyette, of Marseilles, in the *Revue de Chirurgie*, for April 10, 1886, in which the subject is discussed in regard to aneurisms involving the carotid artery and the internal jugular vein, of which he tabulates 16 cases. Combining the statistics contained in this paper with those furnished by Bramann, we have a total of 22 such cases, to which may be added two (or three, if the name "Williamson" given by S. W. Gross, in his paper on "Wounds of the Internal Jugular Vein" in the *American Journal of the Medical Sciences*, for Jan. 1867, be not a misspelling of the name "Wuillaume" given by other authors), making in all 24, or 25, cases of this kind. In most of these cases the treatment was expectant and symptomatic, with the result of recovery or marked improvement. In one case the wound was tamponed and compression applied. This patient recovered. In another case instrumental compression was followed by a cure. In three cases the aneurism was treated by ligation, and only one of the patients recovered. It is noteworthy that all of these operations were done in this country. The first was done by Randolph, in this city; the second was by Prince, in the Army; and the third was done by L. A Stimson, of New York. The latter is the only surgeon who has had a patient to recover after this grave operation.

From this it appears that arterio-venous aneurisms involving the carotid artery and the jugular vein are hardly to be considered amenable to active surgical treatment. The same, it is not necessary to say, is true of such aneurisms within the thorax or abdomen. But when the aneurisms involve the vessels of the extremities, the principles laid down by Bramann may properly be adopted.

MULTIPLE NEURITIS.

From the clinic of Massius, of Liège, Francotte contributes to the *Revue de Médecine*, for May, an important article upon multiple neuritis, a subject which neurologists have recently studied with great care, and, as the paper under consideration shows, with striking results. An affection of the peripheral nerves has been demonstrated in the toxic paralyses, including the alcoholic, in certain cases of tabes, in that curious Japanese disease Beri-Beri, and in the palsies which sometimes follow the specific fevers. There may be widespread involvement of whole groups of nerves, or the affection may be localized; but from the distribution, mode of onset, and symptoms there is not often serious difficulty in excluding a central origin of the affection.

Francotte reports four cases of acute general paralysis, resembling in many respects Landry's ascending paralysis, in two of which the post-mortem examination showed the lesions to be entirely peripheral. The first case was a phthisical patient aged fifty, who for several months complained of feebleness of the legs and lumbar pain, and then, within eight days, became completely paralyzed in the arms and legs, and death took place six days after the onset of the acute symptoms from involvement of the respiratory muscles. In the second case, a woman aged forty-six, the symptoms began with pains in the legs, weakness, with difficulty in walking, and then rapid paralysis with moderate atrophy. The arms became involved, and death took place within a month from the onset of the symptoms. The lesion in these cases was confined to the peripheral nerves, and was of the nature of an atrophic degeneration. The anterior and posterior nerve roots were normal. The third case was in an alcoholic, in whom the paralysis supervened rapidly with pain, became general, and, after an illness of more than a year, the patient was gradually regaining power over the muscles. In the fourth case, that of a woman aged fifty-three, the invasion was rapid, the paralysis of the members was complete, and there was moderate atrophy. After many months recovery gradually took place.

These cases presented many points of resemblance to Landry's acute ascending paralysis, the lesion of which has usually been regarded as spinal, though much doubt exists as to the true nature of the changes. Quite recently Immermann has found acute poliomyelitis in a case with all the symptoms of this affection, while Eisenlohr describes a case which clinically resembled Landry's paralysis, but the lesion was a peripheral polyneuritis. The differential diagnosis between a poliomyelitis anterior and multiple neuritis is certainly difficult in such cases as noted by Francotte. Both affections are characterized by a paralysis beginning in the lower extremities and gradually extending to the arms and trunk, atrophy of moderate grade, and alterations in the electrical contractility. The deep reflexes are abolished, the superficial reflexes are feeble or absent, the cranial nerves are intact, and the sphincters are not involved. These symptoms are common to poliomyelitis and neuritis. The differential signs are: 1st, the more favorable termination in many cases of neuritis; 2d, the parallelism in neuritis between the disturbance of the electrical contractility and the voluntary movements—the presence of the reaction of degeneration, with more or less conservation of voluntary motion, is indicative of a lesion of the anterior horns; 3d, in poliomyelitis the paralysis is localized in certain groups of muscles innervated by different nerves, but associated in the performance of certain movements; 4th, the sensory disturbances, which are marked in most cases of multiple neuritis.

While in typical instances these differential signs may be sufficient to indicate the peripheral or the

central disease, it will frequently be found a matter of no slight difficulty to make a diagnosis. Practitioners will, however, do well to remember that there are cases of multiple neuritis with the clinical picture of an acute ascending paralysis, but with the important difference that they tend, in many instances, to recovery.

THE PULSE IN PREGNANCY, IN LABOR, AND IN CHILDBED.

Dr. Pierre Louge has recently written a monograph entitled *Le Pouls Puerpéral Physiologique*. In it he gives an extension to the word puerperal which is not justified by its etymology, and which is confusing; in this he merely follows the bad example of some eminent French and English writers. He and they include under the term puerperal the state of pregnancy, labor, and lying-in. Such application is permissible so far as labor is concerned, though it would be better to restrict the term to the puerperium, but it certainly is wrong to call the pregnant woman a puerpera. Any one by turning to Andrews' Freund, will find that *puerpera* is defined, first, as a woman in labor or in childbed, then as a lying in woman. It would be quite as correct to include pregnancy in the word puerperium.

But passing from this verbal criticism, let us refer first to the results the author has attained from his examination of the pulse in pregnancy. During the first three months of pregnancy the radial pulse is frequent and regular, the mean frequency being 86. During the second three months the pulse retains the same characters, and becomes fuller and less compressible. During the last three months, the only notable change is that it becomes harder. The pulse of primigravidæ is from 86 to 90, and that of multigravidæ from 80 to 86. The slowest pulse observed was 72, and the most frequent 100.

Jorisenne's "new sign of pregnancy," that is, the invariability of the frequency of the pulse no matter what the position of the subject, lying, sitting, or standing, he has not found true, except occasionally after the fifth month, and at that time other signs of pregnancy generally make the diagnosis easy; beside, this invariability of frequency he has found to occur during menstruation.

The pulse in labor varies during uterine contraction and repose. In the former its frequency increases 15 or 20 beats a minute, and during the latter, it is from 70 to 80.

Soon after the escape of the fœtus, the average frequency of the pulse is 82, the maximum 110, the minimum 62. Contrary to the general statement made by obstetric authorities, during the physiological chill, which in many cases follows the delivery of the placenta, the pulse is increased in frequency, beating from 100 to 120 a minute. This statement needs to be confirmed; we believe that it is exceptional when such increase in frequency occurs.

During the lying-in, the pulse is not in all cases constantly slow. In some patients during the entire period it varies from 72 to 80, never going below the first figure, but sometimes going above the second. In the larger number of cases, however, it oscillates between these limits, but during some of the days, by no means uniform, it momentarily descends to 60 or 58. In still other cases where the pulse was 70 to 84 after the delivery of the placenta, it becomes slow, oscillating between 50 and 46. The secretion of milk is generally established without the form of the pulsation changing, but in many cases there is increased frequency.

Louge has found no connection between the characters of the pulse and uterine regression. While he regards the pulse as furnishing valuable clinical information, he justly judges it inferior in most cases, in this respect, to the temperature—indeed, the thermometer may reveal danger in the lying-in woman whose pulse is not affected.

Louge has taken numerous sphygmographic tracings of the pulse in pregnancy, labor, and in childbed; but these tracings do not prove the increase of vascular tension, generally accepted by obstetricians to be normal in the first two, and by Marey said to occur in the last—an assertion which, though since denied, especially by German observers, ought not to be hastily set aside, considering Marey's well-known accuracy of observation.

OPERATION FOR EXSTROPHY OF THE BLADDER.

Up to the present time the most promising methods of operating for exstrophy of the bladder have been those of Roux and Wood. The former consists in the dissection of a flap from the inner side of the thighs and upper surface of the scrotum, turning this over the mucous surface of the bladder, and making a small opening below, through which the rudiment of the penis is slipped. The free edge of the flap is united to the edge of a suitable incision carried through the skin of the abdomen, and its external raw surface is allowed to heal by granulation, the resulting contraction contributing to the cure of the hernia, which so often accompanies exstrophy. In the method of Wood, a flap is taken from the skin of the abdomen above the exstrophy and turned down. Then a flap is made on each side of the abdomen at the level of the exstrophy, and these are turned over and their edges brought together in the median line. The various edges are then united by sutures, and whatever of the flayed surface of the abdomen cannot be brought together is allowed to heal by granulation. These methods have given as good results as are likely to follow any method resting upon the principle of supplying

Nature's defect, without attempting to correct her error. The latter method, however, must be more likely to succeed, if it can be applied to any case. In the case of exstrophy, we think it may be regarded as an important step in the right direction that Trendelenburg has recently practised, and recommended in the *Centralblatt für Chirurgie*, Dec. 5, 1885, a method which aims to go further toward correcting the congenital defect than does any other.

The most important feature of this method consists in dividing each sacro-iliac synchondrosis, and then pressing together the separated edges of the perpendicular rami of the pubic bone and retaining them in this position with a suitable apparatus. The edges of the mucous membrane are then freshened, the prolapse of the bladder is reduced, the edges of the exstrophy are drawn together with the Lembert suture, and a soft catheter is left in the newly formed cavity to draw off the water through the channel made by the operation. When he suggested this method, Trendelenburg had employed it only once, so far with a satisfactory result. This is enough, however, to recommend it strongly to other surgeons, since it has the merit of being most philosophically conceived.

REVIEWS.

ALPINE WINTER IN ITS MEDICAL ASPECTS, WITH NOTES ON DAVOS PLATZ, WIESEN, ST. MORITZ, AND THE MALOJA. By A. TUCKER WISE, M.D., L.R.C.P., M.R.C.S., etc. Second edition. 8vo. pp. 121. London: J. & A. Churchhill, 1885.

THE present volume, a second edition of the *Alpine Winter Cure*, with changed title, contains a detailed description of the principal winter health-resorts of the Grisons in Switzerland. The intention of the author, as expressed in the preface, to exhibit the remarkable curative and health-giving properties of Alpine climate in their true light, avoiding exaggeration or an omission of those minors details termed "drawbacks," so necessary to be portrayed in the consideration of any foreign or home health-resort has been well carried out, so that the book may be accepted as a safe guide both by patients who are thinking of visiting the Swiss sanitaria and by physicians who are seeking precise information regarding them.

The places described are too distant to be of any advantage to Americans, bu the climatic properties of these resorts which have been extolled as of practical value and application in the treatment of disease, are to be encountered in the vast range of territory on this side of the Atlantic, and whatever advantages are to be derived from the "high altitude cure" can be secured under similar conditions of climate without sending patients across the ocean.

The first chapters of the book describe the places mentioned in the title, as well as the means of access from England. Then follow remarks upon water and soil, atmosphere, therapeutic effects of "cold," on sunlight, barometric pressure, oxygen, ozone, ventilation, and the effects of the climate on the vascularity of the lungs, and on nutrition. Useful practical hints are also given in regard to clothing, diet, exercise, sleep, mode of travelling, etc. The beneficial effects of a pure, cold, dry air are clearly presented. Great stress is laid upon the importance of thorough ventilation and good drainage.

As a large proportion of the time must necessarily be spent in the house, it is essential for the full development of the curative effects of the climate that the air within shall be preserved free from contamination. The want of proper ventilation is one of the principal drawbacks to some of these winter resorts; but this deficiency has been supplied in a notable instance (which it is hoped may be imitated by other hotel proprietors and companies), by the construction on the Maloja plateau of a large Kursaal, fitted with arrangements for the propulsion and extraction of air throughout the building, by which the pure quality of the air breathed within doors is constantly maintained.

The work concludes with notes of meteorological observations, taken at Maloja and other neighboring stations. Dr. Wise's book is interesting and instructive, and can be recommended as a good exposition of what has been termed "the high altitude cure."

SOCIETY PROCEEDINGS.

ASSOCIATION OF AMERICAN PHYSICIANS.

First Annual Meeting, held at Washington, D. C., June 17 and 18, 1886.

(Specially reported for THE MEDICAL NEWS.)

FRIDAY, JUNE 18TH.—SECOND DAY.

MORNING SESSION.

DR. W. COUNCILMAN, of Baltimore, read a paper entitled

CERTAIN ELEMENTS FOUND IN THE BLOOD OF MALARIAL FEVER.

He said that there were certain living organisms found in the blood of persons suffering from malaria, both in the red corpuscles and serum which may be considered pathognomonic of the disease. They are most abundant during or immediately after a chill. They are more difficult to find in fresh than in dry blood, and even in the latter need a high power of the microscope and immersion lenses to be detected. They are amœboid and more rapid in their movements than the white blood-corpuscles, and sometimes contain pigment granules. They are best stained by fuchsine. Besides, there are hyaline bodies found in the blood after death in fatal cases. During the course of his paper he presented many diagrams illustrative of the microscopic appearances of the organisms he had mentioned, many of which were from original drawings from specimens that he himself had prepared. He went minutely into the researches of European observers, and said that he had been entirely unable to verify those of Labaran, whose results do not tally with those of most other observers. Whether these organisms in the blood are the cause or effect of malaria, it is difficult at present to determine. They are not found, however, in healthy blood nor in other diseases. He had acci-

dentally made two control experiments. Specimens of blood from two cases of supposed malaria were presented to him, in which he had failed to discover these organisms. One of these cases afterward turned out to be pneumonia and the other acute tuberculosis.

DR. WILLIAM OSLER, of Philadelphia, said that he had examined the blood in six cases; three during the intervals of the chills, when the patients were under quinine, and three during the chills. The latter cases confirmed the presence in the corpuscles of the bodies in question. The number of the corpuscles containing them is variable. They show very rapid amœboid movements, and there may be several of them in one corpuscle. They look more like hyaline spaces or vacuoles. There are sometimes solid bodies in these spaces which may be microörganisms. In one case, after twenty-four hours there appeared a body in the blood like those described by the Italian observers. He very much doubted whether these so-called amœboid bodies were microorganisms at all. Their behavior and appearance were far more like vacuoles, which might have resulted from irritation of a microörganism in the blood.

DR. GEORGE M. STERNBERG, U. S. A., agreed that there is very much to be learned as to whether a parasite is or is not the cause of malarial fever. He had seen the blood of malarial patients under the microscope, both in Rome and in Baltimore, and was quite satisfied that they could not be vacuoles, but living bodies, for they can be stained, and how could one stain a vacuole? Beside this, we have the hyaline bodies, the spherical forms of which are also stainable. The occurrence of pigment granules in the supposed vacuoles is also an argument against their being merely vacuoles. He has more confidence in Labaran's researches than has Dr. Councilman, as he considers him a thoroughly competent observer, and his results have been verified by another observer. He would say that, having seen the preparation of the Italian observers, and also those of Dr. Councilman, the latter were equal in every respect, if not superior, to the former.

DR. COUNCILMAN, in reply to Dr. Osler, said that if Dr. Osler had stained his preparations, he would have reached different results, and have seen that what appeared in unstained specimens to be separate bodies was really but one body, connected together by a thin film. Their power of being stained shows them to be not vacuoles, but organisms, as does also the fact that they contain pigment granules. In reply to Dr. Sternberg, he would say that he had no doubt that Labaran had really seen the appearances he described, but he thought his explanation of them was wrong, since even the Italian observers had noticed them only four times.

DR. H. N. LYMAN, of Chicago, then read a paper on

TETANY.

He began his paper by describing a remarkable case of tetany in a young man, a printer, aged twenty-eight. He had been delicate for fourteen years; eight years ago had had a hacking cough, which, after continuing a year, was followed by hemorrhage, which recurred frequently for the next two years, varying in quantity from a drachm to several ounces at a time. For the past five years had been in good health, without cough or hemorrhage. In February, 1884, had a paroxysm of shortness of breath, which lasted an hour. In August of the same year had a nervous attack, which lasted five hours, accompanied by convulsive movements of the forearm and hand. In January, 1885, there were severe dyspnœa, hoarseness, pain in temple, haggard expression of countenance, and convulsive movements. The attacks came on at uncertain intervals; they were generally ushered in with a headache, beginning several hours before. They were accompanied by pain in the chest, pain commencing in the right arm and running to the left arm, and opisthotonos. Sometimes the ends of the fingers are drawn together, and sometimes drawn over to the ulnar side of the hand. There is marked dyspnœa, and the voice is affected and remains husky for a good while after the attack has passed off. There is at no time any loss of consciousness, but temporary loss of memory was noticed after a severe seizure. After one attack the right side was partially paralyzed for a certain time. He occasionally suffered from vomiting, and his general health was declining. In his case general remedies were useless; the bromides had no effect, and reliance had to be placed on hypodermatic injections of morphia, assisted by inhalations of chloroform. Trousseau recognized three forms of tetany: First, where the extremities alone were affected; second, where the face and trunk were affected, accompanied by transient swellings; third, greater diffusion and severity of the spasm. In none was there loss of consciousness. A mild form is often seen in little children with summer diarrhœa, where we have only the convulsive bending of the thumb upon the palm of the hand. The disease is more frequent in females or in males with feminine characteristics. The difference between the forms is simply one of degree. Our knowledge of it may be summed up in the statement that it consists of generalized tonic intermittent convulsions of extremities alone, or of extremities and trunk. Any class of muscles may be affected, but the flexors are those most generally attacked. Headache and disorders of digestion are very common. The pain is often severe, but it may be of a sluggish character, or even absent. The sensitiveness of the skin during the attack is increased, and there is at times swelling of the joints. In most cases there is no dyspnœa; there is increased irritability to electricity.

Death is rare except as a consequence of laryngeal spasm. Post-mortem examinations have thus far failed to reveal any pathological changes distinctive of the disorder.

It is most frequently observed at periods where there is instability of the nervous system. Thus it is most frequent in children at the time of teething, again at puberty, during lactation, in persons of sedentary habits, in those possessing rheumatic diathesis, and anything that causes depression of vital powers.

The differential diagnosis is between organic brain disease, epilepsy, professional cramps, Thomsen's disease, ergotism, and tetanus. Organic brain disease can be excluded by the history of the case, epilepsy by the presence of consciousness, by the limbs being affected first, and in the severer stages by the occurrence of opisthotonos. Tetanus is excluded by the absence of trismus and the fact that there is no wound. Professional disease by the history. Thomsen's disease by the latter being congenital. Ergotism is detected by the diet of the patient, and it is an extremely rare

disease. The mild form requires no special treatment. General measures should be employed and the severe attacks treated by narcotics.

DR. JOHN T. CARPENTER, of Pottsville, Pa., thought the causation of tetany was still obscure. He had noticed its association with septic poisoning. The case that first drew his attention to it was that of a child, two years old, with an abscess on the buttocks which had been caused by a sting. There was a cyst-like swelling over the trochanter which discharged an inodorous pus, and then healed. After this the child became restless and sedatives proved useless. Then the eyes became fixed, looking toward the right side, and there was a tonic spasm on the right side. Afterward the fingers of the left hand were drawn tightly together, the spasm being not intermittent but spastic. The spasms returned at intervals in various parts of the body, at one time the mouth having to be pried open. These symptoms were relieved by chloral and chloroform. The child died at the end of a week. There was at no time any loss of consciousness, the family history was good and all the surroundings hygienic. Septicæmia may produce tetany, as in the septic diarrhœa of children, etc.

DR. J. PEYRE PORCHER, of Charleston, S. C., referred to a case where an attack was excited by an attempt to thread a needle.

DR. A. JACOBI, of New York, said that the cases so rarely end in death that we have little opportunity to examine the pathological changes. Meningitis had been found after death, and probably this is the cause of the attacks. Masturbation may be an exciting cause. He had had a patient of his who had noticed this fact in himself. It may be excited by any kind of sexual excitement. Cases of women who have catalepsy on coitus are recorded.

DR. LYMAN thought that Dr. Jacobi's position in regard to meningitis being the cause of tetany too extreme. There is, generally, hyperæmia of the membranes of the cord, but recent observers say there is no definite lesion. In severe cases there is transient loss of memory after the attacks, as in the one he had related, but this may be due to the effect of the medicines used. Sexual excitement is an important exciting cause.

DR. REGINALD H. FITZ, of Boston, read a paper on

THE INFLAMMATORY DISEASES OF THE APPENDIX CÆCI,

which consisted of a very full and accurate analysis of a great number of cases of perforating appendicitis; a disease which, he said, is most apt to affect healthy adult males. It is characterized by sudden severe pain in the abdomen of a previously healthy individual, and is accompanied by chill and nausea. There is generally a point of tenderness on pressure, usually in the right iliac region, but owing to the changes in the position of the appendix it is by no means constantly in that place. It must be differentiated from perityphlitis and inflammation of the cæcum. There is generally a tumor that can be felt, if not by external manipulation, by the rectal touch. There is frequently severe pain on micturition. The extreme gravity of the disease renders an early diagnosis most important, as the operation of laparotomy should be performed as early in the disease as possible. The third day of the disease is not too early and, if the diagnosis is clear, the operation should be performed earlier. The danger lies in the occurrence of general peritonitis. (The paper will appear in full in *The American Journal of the Medical Sciences* for October.)

DR. WILLIAM PEPPER, of Philadelphia, said that two facts had recently come to his notice in connection with appendicitis that had served to illustrate views he had already held. The first was in the case of an autopsy of a man who died of another disease.

During the autopsy he turned his attention to the appendix, as is his custom. The cæcum was normal. There was a small collapsed portion of the appendix and a portion that was stuffed. On section a concretion was found, evidently of old date. Still there was no evidence of irritation. The second fact was developed in the autopsy of a man who had died of perforating appendicitis. He was an extremely active man of business, tall and slender. Although he had employed no physician, his friends had seen that he was in failing health for some time. He was taken sick on a Monday with pain and vomiting. The temperature at first was only a little above normal; it never rose above 102° F. The heart was irregular but not rapid. There was marked pain over the abdomen, but this yielded and became moderate under the use of opiates. There was moderate distention of the abdomen and rigidity till the fourth day of the disease. There were tenesmus and frequent micturition, the urine being clear and copious in character. There had been several evacuations of the bowels at first. There was an indistinct tumor. Collapse occurred on the fifth and death on the seventh day of the disease. The diagnosis was so obscure that it was not made out till too late for an operation to be performed. The autopsy did not reveal peritonitis, but the peritoneum was reddened. There was a singular angularity between the ascending and transverse colon, on the one side of which there was fulness and on the other collapse of the intestine. There was, however, no true constriction. There was plastic lymph around the brim of the pelvis, which circumscribed the pus in the pelvic cavity. The appendix was dilated, thickened, and partly gangrenous. There was a large perforation but no concretion.

The cases illustrate the fact that the acute disease is an explosion of old catarrhal appendicitis. Previous trouble nearly always exists. It is caused by errors of diet, unhygienic habits, etc. The solid bodies which are found are not due to cherry-stones and substances of that kind, as is often supposed, but are true concretions. The difficulties of diagnosis are great. There may be no distinct tumor. The first result of treatment is often encouraging, and therefore helps to increase our liability to overlook the true character of the disease. Early operation is the only chance for saving the patient.

DR. J. T. DANA, of Portland, Me., had found by observation that in cases of simple uncomplicated appendicitis the symptoms are often latent. He referred to the case of a young and promising physician, an *interne* in the Maine General Hospital. On a Friday morning the young doctor had spent two and a half hours with Dr. Dana going the rounds of the hospital. The next morning he was poorly but only felt badly in a general way. Temperature 102.5° F. during the next two days. Sunday the disease rapidly progressed, and he died the next day, seventy-two hours from the first serious symptom.

The autopsy revealed general peritonitis, perforation of the appendix with two flattened concretions, one within and one outside the appendix. Here was a case where the course of the disease was essentially latent. The only prodromic symptoms were that about three weeks previous he had been "bilious" and had apparently recovered after some simple treatment. On the day before he was taken ill, he had had a sudden sense of faintness. This was probably the time when the perforation had occurred. In conclusion, he thought that it was an error to say, as some did, that pain in the region of Poupart's ligament is specially diagnostic of appendicitis any more than of pericæcal abscess. In the case he had related, the young man, who was extremely intelligent, said he could not be sure whether there was increased pain on pressure in any locality, but thought it was rather more in the right iliac region.

DR. LOOMIS, of New York, considered Dr. Fitz's paper a most valuable one as giving us positive data in regard to points of diagnosis. An early diagnosis is extremely difficult, in fact it is impossible by ordinary methods of diagnosis. He thought the occurrence of a chill or of chilly sensations very valuable. Pain, when present is usually, but not always, localized. Some years ago he had determined, in view of the great importance of an early diagnosis, to examine every patient who presented any symptoms pointing to appendicitis, per rectum under chloroform. In the first case of the kind that next presented itself he tried it. There had been a chill the day before. External examination revealed nothing. The examination by the rectum showed an increase in size where it would be expected. Having made out the diagnosis, he advised an operation. It was refused. The patient died on the third day. He had twice since had opportunities of testing the value of the double method of examination. The difficulty is increased by the fact that the vermiform appendix is often out of place, sometimes toward the median line. Then sometimes one part of it and sometimes another is affected. A certain amount of inflammation is necessary to establish a diagnosis. If perforation occurs, unless the treatment be changed to a surgical one, the patient dies. The operation should be done as soon as perforation can be made out, for the danger lies not in the spreading of the inflammation to the peritoneum, but in the escape into the peritoneal cavity of intestinal gas, through the perforation, thus setting up general and fatal peritonitis.

DR. W. W. JOHNSTON, of Washington, D. C., referred to a case that he had seen years since in consultation. The boy had had symptoms of perityphlitis. There was an abdominal tumor. This subsided and examination showed the presence of fluid in the pleural cavity. He was tapped for this and a quantity of purulent fluid was drawn off. The boy was not benefited by the operation, and death followed from exhaustion. The autopsy showed that the pus had come from a perityphlitic abscess, and had extended upward behind the liver. This organ had been compressed by it and had the appearance of having been grooved. The pus had thence made its way through the diaphragm into the pleural sac. This case happened before abdominal operations were considered as safe as they are now.

DR. E. G. JANEWAY, of New York, related the case of a young man who had been attacked by colicky pains. There was some febrile excitement. A careful examination showed that there was either an intestinal abscess or tuberculosis. As the case progressed there were convulsions and coma, and the symptoms rather pointed to tuberculosis. The autopsy showed the appendix glued to the brim of the pelvis. There had been pressure on the ileocæcal vein, which was thrombosed. There were multiple abscesses in liver, brain, etc.

He divided the cases as follows: 1. When general peritonitis is the first symptom noticed; 2. Where there is localized peritonitis; 3. Where there is inflammation of the cellular tissue, with or without abscess.

In the third variety the diagnosis is difficult. There is sometimes in these cases a great deal of œdema with very little or no pus. These may go on to recovery. In the second variety, an operation is necessary.

The varieties must be distinguished. The early symptoms are very much the same. In a certain proportion of cases the pain, though severe, is not localized. There is pain on micturition, and this is sometimes so severe as to simulate the passage of a renal calculus. There is generally some point of deep-seated infiltration and tenderness. He spoke of a case where a large abscess had discharged into the cæcum, resulting in recovery but followed by prolapse.

DR. FITZ, in concluding the discussion, said that incipient appendicitis was so obscure that he had only begun his consideration of the subject with perforation. He agreed with most of what had been said. There are local pain, slight fever, appearance of tumor, a sensitive spot. Palpation must be employed over seat of pain.

The Association then went into

EXECUTIVE SESSION.

DR. HOSMER A. JOHNSON, Chairman of Committee on

PERMANENT ORGANIZATION,

reported that the committee had concluded to recommend the election of the temporary officers to their respective places as permanent officers for the present session. They made the following nominations:

OFFICERS FOR THE ENSUING YEAR,

President.—Dr. S. Weir Mitchell, of Philadelphia.

Vice-Presidents.—Drs. Francis Minot, of Boston, and R. Palmer Howard, of Montreal.

Secretary.—Dr. George L. Peabody, of New York.

Recorder.—Dr. G. T. Whittaker, of Cincinnati.

Treasurer.—Dr. W. W. Johnston, of Washington.

Council.—Drs. Wm. F. Draper, of New York; Robert T. Edes, of Boston; H. M. Lyman, of Chicago; Samuel C. Busey, of Washington; Fred. C. Shattuck, of Boston; Wm. Osler, of Philadelphia; and W. A. Welch, of Baltimore.

DR. WILLIAM PEPPER moved that a committee be appointed to confer with similar committees of other special societies on the advisability of forming an association of all of them under the name of

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS.

Adopted.

The President appointed Drs. Wm. Pepper, R. T. Edes, R. Palmer Howard, J. T. Whittaker, Francis Delafield.

AFTERNOON SESSION.

DR. WILLIAM M. POLK, of New York, read a paper entitled

PERIUTERINE INFLAMMATION.

There are observed in certain cases of uterine disease certain inflammatory masses at the roof, sides, or back of the vagina (very seldom in front), which have frequently been described wrongly under the head of pelvic cellulitis. He proceeded to give a review of the progress of medical opinion on the subject down to the present time. He considered that it is now pretty evident that the principal factor in periuterine inflammation is tubal disease.

What are the causes of these masses? 1. They are the result of salpingitis plus peritonitis. They consist of the tubes, ovaries, connective tissue, etc. 2. Inflammatory masses do not originate from uterus or vagina except after abortion or operation. The starting-point of the process is found, however, in the vagina and uterus. How can the disease extend by the veins, lymphatics, or more directly by the tubes? In septicæmia the process extends by all these paths. That in the case of periuterine inflammation it should extend by way of the tubes is in accordance with analogy. Vaginitis has a tendency to extend to the uterus; why not also to the tubes? The spermatozoa take this course. In the male the course of inflammation and its spread are definite, but how rare it is to find that it causes phlebitis or cellulitis, although it extend as far as the kidney. The inflammation in the female extends in the same way. These arguments, however, being theoretical would not be sufficient alone. In autopsies we find further confirmation. Here, except in cases of septicæmia, cellulitis as secondary to inflammation of the tube is rare. The evidence of the post-mortem room is in favor of the masses in question being the result of salpingitis. It is possible to trace the inflammation along the mucous tracts. As a rule, no thickening of the ligaments is observed, although their appearance might give rise to the idea that there was, owing to a cicatricial condition of the peritoneal covering. There is sometimes found also an enlarged gland. He had made an analysis of fifteen cases of apparent pelvic cellulitis which the post-mortem showed were not this but salpingitis. Owing to the shortness of the time, he only read three of the cases as illustrating his point. The idea that abscess rarely originates in the pelvic cavity is an erroneous one. The etiology of these masses is to be found in endometritis, salpingitis, etc. It is more apt to occur in those who have borne children than in those who have not. Death is a very exceptional result. Where there is septicæmia, or where the system is very much run down, the prognosis is grave. But even abscess may be followed by recovery. The large majority of those affected live. The majority not only live, but recover and bear children. The cure is indicated by disappearance of the masses. When the masses remain, cure is difficult, and when the uterus is movable the disease may be set up again. Sterility in such cases is not uncommon. Whenever there is septicæmia, cellulitis may be present, but still it is not the cause of the masses. In regard to the advisability of removing the tubes, Dr. Polk said that we must bear in mind the difference between the acute and chronic cases. As recovery is very frequent we should be careful about operating. In acute cases surgical means should be resorted to only to cut short general peritonitis. In chronic cases it should be looked upon as a *dernier ressort*. It may sometimes be avoided by tearing up the tubes from the adhesions.

DR. FITZ spoke in confirmation of Dr. Polk's paper. The condition in question was unknown till recently. After the age of fifty it is rare. He thought that cellulitis might be set up by extension.

DR. WM. H. WELCH, of Baltimore, read a paper entitled

AN EXPERIMENTAL STUDY OF GLOMERULO-NEPHRITIS.

In his paper he confined himself to the consideration of the alterations of the Malpighian bodies, beginning with an account of the literature of the subject since the time of Beer, in 1859. This showed, as he pointed out, that there is a great diversity of opinion not only as to the interpretation of the facts observed, but also of the facts themselves.

The following questions have not yet received full and satisfactory answers.

1. What is the origin of the cells which often, in nephritis, occupy the space between the glomerulus and the capsule of Bowman?

2. Does emigration of white blood-corpuscles and diapedesis of red corpuscles take place through the glomerular capillaries?

3. What is the origin of the cells which in many cases are found in large number in the interior of the glomerular capillaries?

4. What *rôle* as to frequency and intensity do changes in the glomeruli play in the pathology of Bright's disease?

With a view of throwing light upon some of these doubtful points by experiments upon animals, he had made a study of nephritis produced by acute cantharidin poisoning with especial reference to the alteration produced in the Malpighian bodies. A description of the structure of the normal glomerulus was then given. His experiments, which are not yet completed, were made upon white rats and rabbits. He used a concentrated solution of cantharidin in acetic ether. He injected subcutaneously in rabbits usually from one-half to one centigramme of cantharidin, and in rats from one to three milligrammes. When a number of injections were made on successive days, smaller doses were used. After the injection of a toxic dose the urine becomes diminished. It contains albumen, hyaline casts, and a large number of leucocytes and red blood-corpuscles. The kidneys appear swollen, congested, and more succulent than normal. In the rat's kidney there are here and there foci of infiltration, with small, round cells, doubtless emigrated white corpuscles. They are most common around the veins at the base of the pyramid, though they are not constantly present. The epithelium of the convoluted tubes is in some places swollen, and the inner parts often broken off, appearing as a granular mass in the lumen of the tubes. At times a number of the cells are devoid of epithelium, and are then pale and homogeneous, and have apparently undergone coagulation-necrosis. The tubes are wider than normal.

In the Malpighian bodies there is a wide space be-

tween the glomerulus and Bowman's capsule partly or wholly filled with cells and a finely granular material. These cells are generally polyhedral and much larger than white blood-corpuscles, they have granular protoplasm and are possessed of oval, vesicular nuclei and are arranged frequently as a concentric mass around the glomerulus. These appearances are similar to those seen in glomerulo-nephritis in man. The explanation usually given for them in the human subject is not applicable here. The cells in this case are not only white blood-corpuscles, but they may be and are derived also from the epithelium of the convoluted tubes with which they are identical in appearance. This is certainly the case with the cantharidin-nephritis in man. The presence of the cells in the capsular space is probably to be explained by their being mechanically pushed from the tube thither. The processes under cantharidin in the rabbit's kidney are, speaking generally, similar to those observed in the rats. He was not inclined to generalize from these researches as to the occurrence in man of this peculiar and hitherto undescribed process, though the possibility that a certain number of cells in the capsular space may be from the epithelium of the convoluted tubes is to be considered.

In his experiments he found that the glomeruli contained an increased number of small, darkly staining nuclei, readily distinguished from the larger and paler nuclei of the epithelium. The former nuclei belong to cells which are either free in the lumen or attached to the inner surface of the capillaries. Some appear to be white corpuscles and others endothelial cells. There is not such a marked accumulation of new intracapillary cells as is observable in the human subject.

Swelling of the endothelium and accumulation of cells in the glomerular capillaries appear to be nearly constant lesions in acute diffuse nephritis of scarlatina. He described the appearance of the kidneys in a man who had had malaria and albuminuria with casts. The chief abnormality found here was that the glomerular capillaries, almost without exception, contained an increased number of cells. In most instances they were widely dilated and filled with variously shaped cells. This was discovered only after very carefully made sections. Important as the changes in the glomerular capillaries are, we are not justified in asserting, as was done by Langhaus, "that these changes constitute the primary and essential lesion of Bright's disease." They are coördinate with the other lesions of diffuse nephritis, and, with our present knowledge, nothing is gained by saying that one of these lesions is primary and essential, and another is secondary and unimportant.

As regards nomenclature, Dr. Welch suggested that, instead of the one term glomerulo-nephritis, the form of disease characterized by an accumulation of cells between the glomerulus and Bowman's capsule be designated desquamative glomerulitis, and that characterized by accumulation of cells or other changes in the interior of the capillaries be called intracapillary glomerulitis; though the question as to whether all these changes are inflammatory is still unsettled.

DR. HENRY F. FORMAD, of Philadelphia, said that in 1881 he had made a series of experiments on rabbits somewhat similar to Dr. Welch's. The changes in the glomeruli, however, were not so carefully noted, but there were cellular formations in the capsules. Still, notwithstanding the use of cantharidin, beyond hyperæmia the changes were remarkably slight. There is a condition of the kidney in man where there is albumen, the appearance of casts and fatty degeneration of the epithelium with atrophy, but with remarkably limited effect in the kidney. It is very common, and may be described as a primary metamorphosis.

DR. HOSMER JOHNSON, of Chicago, agreed that there are many cases indicating grave kidney disease, where the post-mortem does not seem to show sufficient changes in the kidney to account for the disease. He thought Dr. Welch's explanation probably satisfactory.

DR. FRANCIS DELAFIELD, of New York, said that he had never examined cases of nephritis except in man. He thought it a pity that the condition should be spoken of as a special form of glomerulo-nephritus, as changes in the glomeruli are so common in all forms of Bright's disease. This is the case in the simple form, also in cases where there is swelling of the capsular epithelium. Some of these remind one of those just described by Dr. Welch, but they do not advance to the same degree. He had never seen a case where cells had been pushed out of the convoluted tubes. Again we have changes in the capillaries, thickening of their walls, and presence of cells in their vessels. This is very common. Or we may have exudation between the tufts and capsule or excessive growth of the capsular cells, compressing the tuft. This is of the greatest importance clinically, as it is a form of acute Bright's disease which is likely to continue. Even if it be checked, it will sooner or later progress; but even to this form he would not apply the term glomerulo-nephritis or glomerulitis. If there be a form where the glomeruli alone are involved, then such a term would be proper.

DR. A. JACOBI, of New York, asked, Does Dr. Welch mean to say that what he describes is the preparatory stage, and one which will recover? Cases of cantharides poisoning have been reported, resulting in general interstitial inflammation in kidneys and other organs. Was this because too much had been taken?

DR. WELCH said that two Italian observers have found that cantharides administered by the stomach does not cause nephritis, but administered hypodermatically it does. He did not mean to be understood, in using the term glomerulitis, to refer to a distinct disease of the kidney. The term is simply a convenient one to include all cases not degenerative. As to the permanency of the changes, the kind he described have nothing irremediable about them. It is a mistake to try to find out what are the starting-points in Bright's disease, as we cannot discover the relation of the changes to each other. He thought too much emphasis had been laid upon desquamation, and the presence of some swelling in the intercapsular space. The changes in the capillary walls are probably not answerable for albuminuria.

DR. WILLIAM OSLER, of Philadelphia, read a paper entitled

THE BICUSPID CONDITION OF THE SEMILUNAR VALVES.

This condition may be said to exist when two of the three valves are more or less fused. It is a well-recognized abnormality, though not of very common occurrence, and is far more frequently found affecting the aortic than the pulmonary valves. Clinically the cases where the aorta is affected are apt to die suddenly;

they will generally present the symptoms and signs of chronic aortic insufficiency, with hypertrophy of the left ventricle. With the exception of one case where it was noted in an eight months fœtus, the ages at which it has been observed have been between twenty and sixty. This is in marked contrast to those cases in which the pulmonary valves are affected, and which generally die in very early life.

The cause is generally to be traced to intrauterine life and not to the occurrence of endocarditis, but to a want of development.

Dr. George Sternberg, U. S. A., read a paper on

THE BACILLUS OF TYPHOID FEVER,

which will appear in an early number of The Medical News.

Dr. E. C. Seguin, of New York, read a paper entitled

A CLINICAL REPORT OF EIGHT CASES OF HEMIANOPSIA,

which was illustrated by specimens. He spoke of nine cases, five of which were on the right side and four on the left. Three of these he considered by themselves. These patients exhibited coincidently signs of hemiparesis. One showed a post-paralytic chorea, two had alexia or sensory aphasia, in which the patient is unable to understand writing or printing, or if he can, it is only by spelling out the words letter by letter. The majority of cases have no alexia, and there seems to be no essential connection between them. In the remaining six cases, hemianopsia was the only symptom present. In one case aphasia appeared suddenly, but this was entirely distinct from the hemianopsia. In two cases there was progressive weakness of the leg. This was *probably* from a tumor in the cerebrum. He showed by a diagram where the centre for the leg in the brain is. This being the case, a paraplegia of cerebral origin is a possible thing. One case showed neuro-retinitis on ophthalmoscopic examination after the hemianopsia had developed.

He had noted a new symptom in two cases. This was the subjective appearance of hallucinatory images in the half-field before the hemianopsia came on. This is analogous to the changes in the motor centres. There is first irritation and then destruction.

In regard to the pathology, one case was syphilitic, presenting evidence of arteritis with softening on closure of the lumen of the vessel. Two cases were non-specific; two cases had hemorrhage; in two the tissues of the cerebrum were involved; one case had hemorrhage of the cerebral artery. Embolism of the occipital artery is very frequent. In one case there were glaucoma and irregular hemianopsia during the course of the disease. After iridectomy the typical hemianopsia appeared, but he was inclined to consider that the two had no connection with each other. Ophthalmologists have noted that whether the hemianopsia be on the right or left side the point of fixation always escapes. This means that the *macula lutea* is not involved, and this in turn has an important bearing on the course of the fibres supplying the optic nerve, and seems to show that the macula is applied from both sides.

Dr. H. F. Formad, of Philadelphia, gave a demonstration of some

PECULIARITIES OF CYANOTIC INDURATION OF THE KIDNEY.

The peculiarity is one of shape. Thôse who are confirmed drunkards, and die in the debauch, have what he is accustomed to call the *pig-backed* kidney. It is deep red, and is one-third to one-half its normal size; presents a sausage-like appearance; it is elongated and round, and not so hard as when the cyanotic induration is due to chronic heart disease. In his demonstration he excluded all cases where the condition could be traced to cardiac or other organic lesions, and confined himself to the condition observed in those who died in a debauch. Cyanotic induration is produced by any cause interfering with the return of blood. It is produced very easily in the kidneys, since the kidneys lie very near the vena cava, and the renal veins have no valves. When a sudden afflux of blood occurs in an organ it tends to become round, and the kidneys seem to have some erectile power. This change in shape is shown by artificial distention. In cases of heart disease the action is very much more gradual, and the changes being slow, the normal shape of the organ is preserved.

He has had very extensive opportunities for conducting post-mortems in these cases, as all cases of sudden death that occur in Philadelphia are examined by him. In 250 cases of death from pure alcoholism the pig-backed kidney was always present; enlarged liver was observed 120 times; simple cardiac hypertrophy 90 times; cystitis 170 times; cirrhosis of the liver, with contraction, only 6 times. This last is extremely remarkable, in view of the fact that it is usually considered to be one of the most usual lesions in drunkards.

As the time far adjournment had now arrived, the following papers were read by title: *Notes of a Case of Hepatico-bronchial Fistula*, by Dr. J. E. Graham, of Toronto; *Pancreatic Hemorrhage as a Cause of Sudden Death*, by W. F. Draper, M.D., of Boston; and *Pernicious Anæmia*, by Dr. A. Jacobi, of New York.

After votes of thanks to the authorities of the Army Medical Department for the use of the room, to the profession of Washington for their hospitality, and to the officers of the Association for their efficient services, the Association adjourned.

COLLEGE OF PHYSICIANS OF PHILADELPHIA.

Stated Meeting, May 5, 1886.

The President, S. Weir Mitchell, M.D., in the Chair.

Dr. J. Solis Cohen read a paper on

THREE CASES OF PRESSURE UPON THE RECURRENT LARYNGEAL NERVE FROM DIFFERENT CAUSES, WITH FIXATION OF THE LEFT VOCAL BAND IN THE PHONATORY POSITION.

Dr. Cohen referred to the uncertainty surrounding the central innervation of the laryngeal muscles for their antagonistic function of opening and closing the glottis. Although if both of the two doors that admit the breath of life remain closed, life becomes extinct in at most two minutes, yet if only one of them is shut the interference with respiration may be too slight to attract attention. When a vocal band stands at rest in the position normally occupied during phonation only, the

question arises whether that fixed position is due to tonic spasm of the muscles which close the glottis on that side, or whether it is the result of paralysis of the muscles which hold the glottis open. The view generally entertained and endorsed by laryngolgists is the one promulgated by Dr. Felix Seman, of London, that organic disease of the roots or trunks of the motor nerves of the larynx is likely to become earliest and sometimes exclusively manifested in paralysis of the posterior cricoarytenoideus, the dilating muscle. The lecturer was more inclined to accord with the opposite opinion announced by Dr. Herman Krause, of Berlin, based on clinical observation, on neural analogy, and on physiological experiment. In its briefest expression this view maintains that, in analogy with neurotic manifestations in other portions of the body, organic irritation of the recurrent laryngeal nerve produces spasm of all the muscles supplied by its fibres, both those which preside over the patency of the chink of the glottis for respiratory purposes, and those which preside over the approximation of its edges for purposes of phonation, cough, and expulsion of foreign material: but that, inasmuch as the number and mass of muscle and nerve fibres preponderate in the domain for closure, the equilibrium maintained by the respiratory centre under normal conditions is overpowered, so that the spasm remains manifest in the closing phase only, despite the coexistent spasm of the weaker dilator muscle. The opinion held, then, is that the phenomenon of permanent fixation is due to the overpowering contracture or tonic spasm of constricting muscles of the larynx, and not to a paralysis of a dilating one. The atrophy of the dilating muscle is attributed to its mechanical immobily, and not to its paralytic immobility. On the other hand, those who believe in primary paralysis of the dilator muscle consider this spasm to be a secondary contracture, and not a primary one.

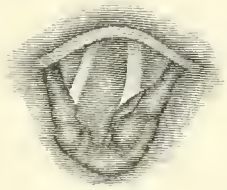
Aneurism of the arch of the aorta and of the left subclavian artery with fixation—spastic immobility?—of the left vocal band in the phonatory position.—Mr. X. Y. Z., æt. forty-four, formerly a corporal of artillery, and since June, 1865, a machinist, applied November 15, 1885, at the Philadelphia Polyclinic on account of great dyspnœa said to have been of but six months' duration, although shortness of breath had existed for fully five years, eventually accompanied with frequent cough, and expectoration of frothy white mucus. Coughing produced great pain within the left side of the thorax. Pains in other regions were referred to.

Dizziness in walking had been produced for some months, compelling interruptions for rest. Dizziness was nearly as bad on standing. About five years before, the voice began to undergo change. It was now weak and diphthonic, the higher pitched tone being metallically shrill and squeaky. Respiration was embarrassed spasmodically on exertion, but during rest in the sitting position was fairly quiet at a rate of from twenty to twenty-four per minute. The patient felt much better in the open air than in a room. The pulse was about 86 per minute at the right wrist and over a pulsatile, expansile tumor below the clavicle and second rib of the left side, but it was almost imperceptible and apparently irregularly intermittent at the left wrist. The pupils were equally dilated.

There was a history of inflammatory rheumatism in 1866, with subsequent histories of intermittent fever and of the primary lesion of syphilis. Appetite and digestion were reported good, with irregularly constipated habit. Emaciation was steadily progressive.

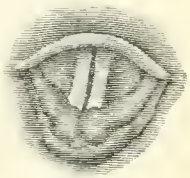
Physical exploration of the thorax revealed aneurism of the arch of the aorta and of the left subclavian artery. Laryngoscopic inspection revealed tense immobility of the left vocal band in the phonatory position—or rather, with its posterior extremity, a fraction of a line beyond the middle of the glottis, with slightly concave or semielliptic outline of the immovable vocal band (Fig. 1) representing the left half of the ellipse normally produced by the simultaneous action of the two sides in phonation (Fig. 2). The aneurism of the aorta

Fig. 1



In respiration.

Fig. 2.



In phonation.

compressing the inferior laryngeal nerve as it winds around the arch of that vessel in its recurrent course to the larynx, explained the cause of the fixed position of the vocal band. This fixed position was attributed to preponderating spasm of the group of adductor muscles rather than to paralysis of the single abductor, because of the shrillness of the voice, and the presence of an over-tense vocal band to account for that shrillness or increase of pitch; complete tension requiring contraction and not relaxation of the posterior cricoarytenoid muscle. The patient, who had passed out of his hands, died suddenly while walking in a garden on April 12th, but the manner of death is unknown, whether by spasm of the glottis or by rupture of the aneurism, probably by the latter. The physician summoned after death suspected disease of the heart.

A second patient with a similar permanent fixture of his left vocal band in the phonatory position was exhibited, his phonic tone not being shrill as in the other case, but apparently normal; as is usual in these instances, the question as to contracture or paralysis could find no answer in his voice. There was no aneurism detectable in the chest of this man; but that there may be aneurism pressing posteriorly on the recurrent nerve without physical evidences on auscultation has been proved not only by a post-mortem examination in a case of the lecturer's[1] in which such a correct diagnosis had been made by exclusion in a man with a similar laryngeal defect; but by similar post-mortem discoveries by others. In this case, however, the fixture was not attributed to aneurism, but to another source of irritation, while the inference of contracture was based upon the occasional presence of tremors and even of spasms in the right vocal band, so that at moments the complete picture of the bilateral malady is manifest for a few seconds.

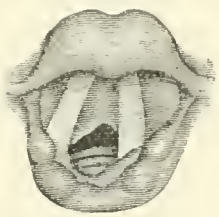
Some eight or more years ago Dr. Cohen reported a

[1] Amer. Journ. Med. Sci., July, 1883, p. 89.

case of permanent bilateral involvement of this kind preceded by the unilateral lesion. This patient died a few weeks ago, and the structures implicated, muscular and nervous, are undergoing study by Prof. Osler. It seemed probable that the case presented might become a similar instance of bilateral lesion following a unilateral one.

Fixation of left vocal band in the phonatory position, with tracheal constriction from enlarged thyroid body, and occasional spasm of the mobile vocal band of the right side.—X. Y. Z., æt. forty-four, an old private of three years military service; of late years a longshoreman, accustomed to heavy work, lifting large bales of merchandise, applied to the Polyclinic with great dyspnœa and marked tracheal stridor, chiefly inspiratory; with a history of continuous difficulty of breathing preventing sleep, and frequent suffocative attacks of spasm of the glottis especially at night. About one year before, while working actively in a place much exposed to draught, he began to get very hoarse so that he could barely whisper, but he had no fever and no embarrassment in respiration. Cough and expectoration ensued. In about a month his voice began to improve and became gradually restored, but cough and expectoration continued. About August last breathing became embarrassed, became associated with wheezing, and attended with a sense of weight at the epigastrium. This embarrassment in respiration steadily augmented. Just before applying at the Polyclinic, dysphagia became added to his symptoms, and he almost choked when taking food whether solids or liquids. The great stridor made laryngoscopic inspection the first step in investigation. The left vocal band was found fixed in the phonatory position. (Fig. 3.) Both bands were congested and thickened. The right band and other laryn-

Fig. 3.



Fixation of left vocal band in phonatory position, with involution of tracheal wall of same side.

geal structures moved freely and normally in respiration and phonation, and on phonation even the supra-arytenoid cartilage of the affected side became bent inward and forward. The great stridor could not be accounted for by the encroachments upon the open glottis, for one-half was entirely normal in proportions and presented ample room for free respiration. Pressure on the trachea was, therefore, suspected, and further inspection revealed an involution of the tracheal wall on the left side and extending anteriorly. External examination of the neck revealed an indurated enlargement of the left side of the thyroid gland of the size of a walnut. The inference following was, that the left lobe of the thyroid body dipped down so as to press both upon the trachea and upon the recurrent nerve; hence the immobile condition of the left vocal band, and the tracheal stridor. Tendon reflexes were normal. There was slight bilateral relaxation of the palate which did not respond to titillation. Physical examination of the chest revealed small scattered bilateral areas of bronchial breathing most marked along the course of the primitive bronchi. These were attributed to the interruption of the normal tracheal sounds by the involution of the tube acting as a tumor or foreign body. Emphysema existed at the upper part of the left lung, most marked behind. The cardiac impulse was felt at the epigastrium. There was some insufficiency of the mitral valve. No evidence of aneurism could be elicited.

The family and personal history were negative. Nevertheless twenty grain doses of potassium iodide were given three times a day, with marked benefit from the very first; and within a few days dysphagia ceased, tracheal stridor ceased, dyspnœa disappeared except on exertion, and the thyroid gland underwent resolution until now its enlargement is hardly patent to inspection though distinctly perceptible to palpation, especially during movements of deglutition. Involution of the tracheal wall can still be made out on laryngoscopy; the left vocal band is still fixed in the middle line, but the mobility of the supra-arytenoid cartilage has apparently ceased. Within a fortnight or so it was noticed on several occasions that, under the excitement of instructions to phonate strongly or rapidly, or to make deep and rapid inspirations, the hitherto unimpaired vocal band of the right side is sometimes tremulously inobedient to the will, and that once in a while it occupies the middle line for a few seconds despite the strongest efforts at inspiration, which, in fact, increase the difficulty, and produce that characteristic stridor in inspiration which accompanies the bilateral condition under consideration. Certainly the temporary closure of the glottis is at present due to clonic spasm of the adductors of the hitherto sound side of the larynx. Whether this participation of the sound side is indicative of the encroachment of a central lesion which has hitherto been unilateral, or whether it is indicative of reflex motor disturbance from involvement of the sensory fibres of the pneumogastric of the side primarily affected, a local lesion first affecting the recurrent fibres only and subsequently the other fibres of the pneumogastric, is a question for future study.

A third instance of fixation of the left vocal band, due to another cause, recently came under notice accidentally, as indeed have several instances before.

Fixation of left vocal band in phonatory position, following left-sided pleuritic effusion with displacement of the heart—A young gentleman, nineteen years of age, was sent to the lecturer recently for inquiry as to the cause of a hoarseness of several weeks' duration. In addition to evidences of a passing laryngitis, which had produced the hoarseness, the left vocal band was fixed in the middle line as in the other cases narrated. The hoarseness had passed away, voice was nearly normal, both the vocal bands remained immobile in the median line. There was a history of left-sided pleurisy three years ago with effusion enough to push the heart to the right side. The region of the heart was rather prominent, there was slight dulness just below the upper third of the sternum, the sound of the tricuspid valve was loudest just to the right of the sternum, and the other physical signs were of negative value. The theory at present entertained, for the case had not been thoroughly studied

out, was that the displacement of the heart to the right and its probable hypertrophy had caused a strain upon the recurrent nerve by dragging the arch of the aorta forward, downward, and to the right, which had either developed a neuritis resulting in neuropathic contracture, or some adhesions of connective tissue or enlarged bronchial glands. Pressure by such swollen glands might induce such a neuritis. In either instance the physical condition of the larynx had nothing to do with the cause of the hoarseness on account of which the interior of the organ was originally inspected.

This case illustrates the fact that when one vocal band is fixed in the middle line, the condition, however serious may be the lesion which has occasioned it, may remain undetected indefinitely. It does not interfere with respiration, for half a glottis is amply sufficient for that function. It does not impair the voice, for the immobile band is in the very best position for good phonation.

Given a vocal band fixed in the middle line in consequence of irritation upon the recurrent nerve, would this be due to spasmodic contracture of the entire group of muscles, or to simple overaction of the adductor portion of that group, because the abductor has become paralyzed?

That tremor precedes spasm is seen in the second case narrated; analogically to what has been witnessed in experiments upon the recurrent nerves, as performed by Krause and others, when fibrillary tremors precede the well-known traction of the vocal band to the middle line.

The great office of the laryngeal nerves is to secure space for respiration, their auxiliary office is to provide means for phonation and cough. While it seems, *à priori*, suitable that the importance of the dilators of the glottis should have caused them to be invested with special immunity, rather than with special vulnerability, it may be argued, on the other hand, that as the main office of the motor laryngeal nerves is to maintain the patency of the glottis for breathing purposes, serious injury to those nerves would compromise the integrity of that office. The reply to this argument would be, that an injury completely destructive of the conductivity of the nerve, leaves the vocal band immobile in a position which does not interfere with the respiratory function.

The speaker then referred to a hypothetical explanation for these apparent contradictions based upon general physiological principles offered by his brother, Dr. Solomon Solis Cohen. It adopts, in a modified form, the as yet undemonstrated theory of the existence of a cortical motor centre for the larynx, and assumes that the respiratory (abductor) fibres of the recurrent nerve offer less resistance to the passage of nerve-currents than do the phonatory (adductor) fibres; an assumption made highly probable by the ascertained laws of nerve-resistance. The direct energization of a muscle of a limb, it is well known, proceeds via an anterior nerve-root from the motor cells of the gray matter of the spinal cord—which may be compared to the local battery in a telegraph line—while the impulse which liberates this energy in obedience to the will, proceeds from a centre for voluntary motion in the cerebral cortex—the line battery. It may also be set free by so-called reflex action, under the stimulus conveyed from the periphery by an afferent nerve; the peripheral impression becoming the line battery. Applying these facts and hypotheses to the larynx, the following conclusions are drawn. The local battery for laryngeal motion is the nucleus of the spinal accessory nerve in the fourth ventricle. From this proceed two sets of fibres, one, of low resistance, to the dilator muscles, another, of higher resistance, to the constrictor muscles. The ordinary dilatation of the glottis for respiration, which is accomplished by a partial contraction of the dilator muscles, is an automatic function of organic life, under the control of the respiratory centre in the medulla, and takes place with the liberation of the minimum amount of energy by the central motor cells. The respiratory impulses continuously traverse the recurrent nerve, and all other impulses become superimposed upon them. The effect of a first additional increment of nerve-force, which may be set free under psychic impulse from the cortex, is to stimulate further the dilator muscles, opening the glottis wider or to its full extent, as in forced inspiration. More intense psychic stimulation, awakening sufficient energy to overcome the resistance of the adductor fibres of the recurrent nerve, elicits in addition to the continuing action of the dilator muscles (which is necessary to complete the tension of the vocal bands posteriorly) the response of the constricting muscles, and the vocal bands are brought into position for phonation. Reflex stimulation of the centre by an afferent nerve, excites the coughing action of the constricting muscles.

If this explanation of the normal action of the vocal bands be correct, the positions they assume under pathological conditions become easily explicable.

An irritative lesion of the nerve tract, or of the centre, or such lesion of the cortex or of the (hypothetical) cortico-medullar tract as should remove psychic control from nuclear cells continuing to generate nervous force, would produce according to its degree, at one extreme, increased action of the dilating muscle (position of forced inspiration, extreme abduction), or at the other extreme, spasm of all the muscles, bringing the vocal bands into the phonatory position (complete adduction), and between these extremes would be the various manifestations of tremor, spasmodic cough, and even equilibrium (non-paralytic) in the cadaveric position.

In depressive lesions, when the nervous current is too weak to overcome the resistance of the adductor nerve fibres—as when the will fails in hysteria—or when there is partial interference with the generation or transmission of nerve-currents, as in some cases of disease or injury of the nerve tract, the constricting muscles would receive little or no influence, the dilating muscles would continue to act, and there would be presented the well-known picture of adductor paralysis, best exhibited in hysterical aphonia. In hysteria, perfect cough is still possible under reflex stimulation. In organic diseases presenting the same picture, cough should be impaired, but not absent, as organic disease of this nature is not likely to be bilateral.

Destructive lesions of tract or nucleus, if complete, cut off entirely the nervous stimulation; all the muscles fail to act; and the vocal bands are left in the cadaveric position (paralytic, complete relaxation).

This hypothesis, for the sake of simplicity, omits to take account of normal or pathological inhibition of respiratory acts, or of a possible complication offered by the unknown relations of the sympathetic system with the laryngeal function of respiration.

ONTARIO MEDICAL ASSOCIATION.

Sixth Annual Meeting, held at Toronto, June 2 and 3, 1886.

(Specially reported for THE MEDICAL NEWS.)

WEDNESDAY, JUNE 2.—FIRST DAY.

THE sixth annual meeting of this Association was convened in the public hall of the Education Department at Toronto, at 10 A.M., THE PRESIDENT, G. A. LYE, M.D., of Chatham, being in the Chair.

Over one hundred and fifty members from different parts of the Province were present, besides several guests from other Provinces and the United States. The meeting was the most successful ever held by the Association. The morning session was spent in routine business.

AFTERNOON SESSION.

RECEPTION OF GUESTS.

THE PRESIDENT expressed the pleasure it gave them to welcome their guests, among whom were several from across the border; but true medicine is a brotherhood which knows no dividing lines.

The following guests were then introduced: Dr. E. M. Moore, of Rochester, President of New York State Medical Association; Drs. Cronyn and Tremaine, of Buffalo; Dr. Manton, of Detroit; and Drs. Trenholme, Ross, and Rodgers, of Montreal.

DR. POWELL, of Toronto, moved that the President be requested to convey, by telegraph, an expression of the fraternal

GREETINGS TO THE OHIO STATE MEDICAL SOCIETY,

now in session at Akron.

THE PRESIDENT then delivered his

ANNUAL ADDRESS.

After returning thanks for the honor conferred upon him by his election to the Chair, he pointed out the advantages to be derived by the profession from such an association as this. It is a source of much pleasure and gratification that our system of medical education is already so complete and that our graduates are second to none. There is, however, abundance of time and ability to reach still higher grades, and it is a matter of deep regret that the colleges graduate in three terms, and that our anomalous medical relations with the Mother Country oblige our council to accept three years. This matter might engage the attention of the Association. It is the duty of that Association to watch well the course of medical education, to suggest improvements and to let them be known for the guidance of those in authority.

DRS. GIBSON and YONKER, of Belleville, then showed two patients suffering from

HÆMATURIA

for a prolonged period. The most thorough investigation had failed to discover the cause in either case. Treatment on general principles had been without effect.

DR. ATHERTON, of Toronto, then opened the discussion on

FRACTURES OF THE FEMUR,

the subject selected for discussion by the Committee on Surgery as a substitute for an annual report on surgery.

After dealing with the classification, etiology, diagnosis, and prognosis of the various fractures to which this bone is liable, Dr. Atherton gave a full outline of the general principles of treatment, and emphasized the following conclusions: 1. Always insist on having a good, firm mattress, to prevent sagging of any part. 2. Remove the footboard of the bedstead, so as to have no obstruction to the downward movement of the body, which is apt to take place by traction of the weight. 3. Apply the strips of plaster exactly along the lateral median line, and see that they extend as far up as the fracture, so as to relieve the strain upon the ligaments. 4. Bandage the limb from the toes up. 5. Place a cushion of folded blanket, or other suitable material, between the heel and calf, so as to avoid ulceration of the former from pressure on bed. 6. Test position of pulley, so as to insure traction on line of limb, or a little above that line. 7. When a long external splint is used, pad well above the external malleolus, so as to protect it. 8. Maintain steady traction on limb till everything is in readiness for attachment of the weight. In conclusion, he thought all cases in which existence of fracture is doubtful, should be treated as fracture.

DR. MCFARLANE, of Toronto, said he was disappointed in that the paper did not deal with the special difficulties met with in many cases, such as compound comminuted fractures, distinction between intracapsular and extracapsular fractures of neck, etc., instead of the general management of ordinary cases. He advocated the use of plaster dressings in all cases, as with them he had had almost uniform good results, with seldom over half an inch shortening. In compound fractures he left a fenestrum at seat of wound through which to wash it out frequently—as often as four or five times a day, in some cases.

DR. OLDRIGHT, of Toronto, pointed out the necessity of great care being taken to prevent tilting of the pelvis when making measurements, else the measurements will indicate apparent shortening when the pelvis is tilted toward the side of fracture, when none really exists, and the converse when the pelvis is tilted to the opposite side. He cited a case that occurred in his own practice, to illustrate the truth of this statement. Since then he has provided against such tilting of the pelvis by using a T, placing the crossbar on the anterior superior spines of the ilium.

DR. POWELL, of Toronto, pointed out that, in taking measurements, the tape should pass over the thumb-nail, and the nail then placed in the notch below the iliac spine.

DR. MOORE, of Rochester, referred to the controversy that was long waged between Sir Astley Cooper and Dupuytren, as to whether in intracapsular fracture there could be bony union. In his opinion the question has no effect on treatment, because he thought many cases of intracapsular and extracapsular fractures cannot be diagnosticated. They may appear to be intracapsular at first, but a few days later prove to be extracapsular. Their differentiation is of no moment. From the attachment of the capsular ligament to the neck of the femur there passes up to the margin of the articular surface a strong reflection from the capsular ligament, which is intimately incorporated with the periosteum. This reflected ligament is usually not torn. He cited two cases in which, death occurring within a short time

of fracture, post-mortem examination proved the truth of this statement. In neither of these cases was there scarcely appreciable shortening—not more than half an inch. If left to nature, this reflected ligament soon gives way, and marked shortening occurs. In making measurements, he does not trust to his own feeling as to the position of the nail at the iliac spine, but places an assistant with a thumb-nail in the notch below each spine, and measures from the thumb-nails. We should take advantage of the untorn condition of the reflected ligament, and put on just sufficient weight to overcome the contraction of the muscles, then the reflected ligament will hold the fragments of the bone together. The amount of weight to be attached is to be wholly governed by the sensations of the patient—only using sufficient tension to make him comfortable; more will cause spasm of the muscles, and less will not overcome their contraction; in either case the fragments will be disturbed. He pointed out that eversion is usually slight at first, but there is always some.

Dr. Tremaine, of Buffalo, thought the subject a very practical one, as so many suits for malpractice are brought, on account of deformity following fractures of this bone. He said it was scarcely fair for hospital surgeons to compare their results with those of practitioners who saw only the few likely to be met with in private practice. In the treatment of these fractures as in all others perfect coaptation is the most essential point, and for maintaining the coaptation he thought plaster dressing the best agent. It was unfortunate that it had been condemned by so widely accepted an authority as Hamilton. He strongly disapproved of the practice of frequently washing out of the wound in compound fractures. The parts require physiological rest. The wound should be thoroughly cleansed and then dressed antiseptically.

Dr. Carson, of Toronto, referred to the almost uniformly good results obtained by Syme, by the use of simple coaptation splints. He thought compression by these splints overcame contraction of the muscles better than extension.

Dr. Richardson, of Toronto, protested against the wholesale condemnation of plaster dressings by Hamilton. It is immaterial what is used so long as coaptation is maintained, and that may be attained in many cases by either the inclined plane or straight splint. Any plan requires the exercise of common sense. He also protested most emphatically against the assertion that uniformly good results can be obtained by any plan of treatment. These statements had been the cause of disaster to many a capable, conscientious practitioner in most unjust prosecutions.

Dr. Campbell, of Seaforth, then presented a report on

TWO CASES OF PLACENTA PRÆVIA, WITH REMARKS.

One was delivered at six months and the other at seven. After hemorrhage first developed the cases were closely watched, but gestation was not terminated till the loss of blood became dangerous; when tamponing of vagina was resorted to. Both women made good recoveries. Sponge tents or Barnes's bags might be used to dilate the cervix in such cases, stopping hemorrhage at the same time.

Dr. Temple, of Toronto, was of opinion that so soon as you are convinced of the existence of placenta prævia so soon should you terminate gestation. The dangers are too great to allow a temporizing course to be followed. He thought resort to the vaginal tampon a very unsafe method to adopt for arrest of hemorrhage, as fatal hemorrhage might occur behind the plug and into the uterus without any blood appearing externally. He had seen such cases. He could not commend sponge tents for dilatation of the cervix; they are two slow. Barnes had pointed out very clearly that we should rupture the membranes or separate the placenta from its attachment to the cervical zone. This arrested hemorrhage by pressure of the head by the first method, and by closure of the ruptured vessels by contraction of the uterus in the second. Turning was then usually unnecessary.

Dr. Trenholme, of Montreal, said we cannot lay down hard-fast lines to be applied to all cases—each must be treated on its own merits. In city practice, we may temporize; many cases have gone on to term, a living child being born. In some, hemorrhage is so severe that gestation must be terminated at once. Turning is suitable in such cases. He advocated the use of the tampon in all cases in which there was not special urgency.

Dr. Canniff, of Toronto, was convinced that the plug, if properly applied and maintained, is effective in arresting hemorrhage and permits of the accoucheur being absent for some time with perfect safety. He strongly urged the impropriety of interfering with gestation unless the case be urgent; the child's life should be forfeited only for gravest causes.

Evening Session.

Dr. Gillies, of Seeswater, read a paper on

PNEUMONIA.

From the report of the Registrar-General of the Province he culled statistics showing the death-rate from this disease for several years. The causes were then discussed. As to the nature of the disease, he was inclined to look upon it as a specific fever rather than a local affection with symptomatic pyrexia. The treatment should be conducted on broad general principles; "generalize the disease, but individualize the patient." Some cases require sedatives; some stimulants; and others nothing. The two special sources of danger in all severe cases were from heart failure and the pyrexia. Both should be closely watched.

Dr. Geikie, of Toronto, followed in a long address on the treatment. He advocated venesection in well-marked sthenic cases. Few such cases are seen in cities, hence the condemnation of bleeding by many authorities. Bleeding should be followed by tartar emetic in small doses as a depressant, with opium to relieve pain. Here abstinence should be practised, or very little light nourishment taken till over-action is controlled, when fuller diet with tonics should be given. In mild cases but little depressant remedies should be used, while the asthenic require stimulants from the first.

Dr. Smith, of Seaforth, used cotton-wool instead of poultices, which are apt, from being improperly made and allowed to become cold, to do injury. He opposed the use of antimony as adding to the work of an already burdened heart. He thought quinine the best agent for controlling temperature.

DR. GRAHAM, of Toronto, said that morbid anatomy gives very imperfect ideas of the diseased processes in many diseases. This is very evident in skin diseases in which the appearances before and after death usually differ so widely. He thought the best classification is into sthenic, creeping, and septic varieties. In the large majority of cases the disease is a specific fever. Some are, however, simply local inflammations with symptomatic fever. This view was as old as Laennec, who taught that in cases in which the local inflammation is small with severe constitutional disturbance, the disease is a general one. Inflammation is a vital process, and it is doubtful whether aconite, veratrum viride, etc., have any influence over its progress. Contrary to the preceding speaker, he thought stimulants useful in many cases, as they limit tissue change rather than increase it. In the treatment of all cases the state of the heart should receive special attention. The obstructed pulmonary circulation, lessened respiratory surface, lessened thoracic movement, the pyrexia, and the specific poison, all tend to weaken the heart. The pyrexia can best be controlled by quinine. In septic and creeping cases, tinctura ferri muriatis with stimulants gives best results. Blisters, though not in accordance with theory, are often of great benefit in clearing up a consolidated lung after the acute stage is past.

DR. ROSS, of Montreal, said that no subject deserves more attention as to nature, causation, treatment, etc., in this climate than pneumonia. The discussion this evening had called forth widely different views. Many cases with extensive consolidation, in which the pyrexia is mild, make good recoveries, while others, with high fever and small amount of consolidation, terminate fatally. It is in this line we are to seek to solve the question of treatment. Quinine, in antipyretic doses, has disappointed him. There is no doubt that it has done a great deal of harm. Besides being liable to be followed by evil effects of itself, it is unlikely that it has any effect on the disease; we cannot produce any artificial reduction of temperature by quinine of lasting benefit, especially if not given till the sixth or seventh day. Bleeding late in the disease may be called for when there is extensive consolidation with overloading of the right heart. In conjunction with Dr. Osler, he had resorted to venesection in such a case. The result was altogether satisfactory. He has pursued the same course with other cases since then. The effect is to give mechanical relief to an overloaded nervous system.

Dr. Clark, of Walkerton, and Dr. Carniff, of Toronto, also took part in the discussion.

DR. MCKEOUGH, of Chatham, presented a paper on

THE INFLUENCE OF MALARIA AND QUININE ON PREGNANT WOMEN,

of which the following are the conclusions:

1. Gestation affords no immunity from malaria; it rather renders the woman more susceptible. Of 228 pregnant women under his observation, 36 were affected with malaria.

2. Malarial poisoning tends to induce miscarriage. Of the 36 cases of malaria in pregnancy, 17 miscarried. These figures agree with those of various authorities. As to the cause of abortion opinions vary.

3. Quinine has no tendency to produce abortion in the large majority of cases; exceptionally it causes miscarriage just as occasionally it induces a cutaneous rash.

4. Parturition has a tendency to prolong the malarial attack, notwithstanding the administration of quinine.

DR. HOWE, of Buffalo, gave a short demonstration of cultures and methods in relation to bacteria.

To be concluded.)

THE PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, April 26, 1886.

THE PRESIDENT, S. WEIR MITCHELL, M.D., IN THE CHAIR.

DR. H. F. FORMAD, by invitation, read a paper and presented specimens illustrating

DIFFERENT FORMS OF CEREBRAL HEMORRHAGE.

(See THE MEDICAL NEWS, June 5, page 639.)

DR. DERCUM said that Dr. Formad states that in no case can the blood find its way from the pia mater into the ventricles. That is true of the general surface of the brain, but not of the base. Profuse hemorrhage at the base may find its way into the lateral and third ventricles through the transverse fissure of the brain; of this he had seen an instance.

DR. CHARLES K. MILLS thought that perhaps the statement in regard to the first class of cases may be misleading, if he says absolutely that small hemorrhages in the fourth ventricle and in the lateral ventricle occur only from traumatism. These are of frequent occurrence, particularly in the floor of the fourth ventricle in many diseases. They probably take place at the time of death. He has seen them in cases dying in the epileptic status. They have been found in cases supposed to be hydrophobic.

The occurrence of the hemorrhage in the second class of cases opposite the point of application of the force is interesting, and he thinks is best explained by Duret in his papers on traumatisms. He attributes it to displacement of the cerebrospinal fluid with the formation of numerous vacuoles and the rupture of the bloodvessels from within outward, the largest vacuoles usually occurring opposite the seat of injury. In those cases in which the hemorrhage is in the lenticular body and works its way into the lateral ventricle, numerous ecchymoses occur in various parts of the membranes and of the brain. These occur for the same reason as when the skull is struck from the outside.

He believes that in children hemorrhages occur beneath the pia mater without any special recognizable cause. He has seen one case in which meningeal hemorrhage occurred in a newborn child, probably as a result of traumatism from the use of forceps. Where children die soon after delivery, he believes that death is sometimes due to this cause.

DR. CHARLES K. MILLS reported

A CASE OF UNILATERAL SWEATING.

The patient was an unmarried woman thirty-four years old, sent to him by Dr. Deakyne. Eighteen or nineteen years ago she began to have spasmodic attacks which seemed, from description, to be epileptic. About fourteen years ago she had a stroke of left-sided paresis. About the same time she began to perspire excessively on the side of the paresis. This unilateral sweating has continued up to the present time and is more marked

than before. The secretion on the right side is normal. There is also increased lachrymation on the left side. The saliva seems to be in about equal amount on both sides. Before the occurrence of the spasms she complained of a peculiar taste, probably metallic. She occasionally has slight attacks of dizziness, is somewhat absent-minded, and at one time had severe pain in the head. Four years ago the spasms ceased. The left side of the mouth is visibly drawn a little upward. There is slight paresis of the muscles supplied by the facial nerve. She cannot draw up the left side of the mouth volitionally as well as the right. The slight loss of power in the limbs of the left side is more particularly in the arm.

She has had no trouble with the bladder or bowels. At times the left side of the face reddens very much and remains so for some time. She has some pain on the left side. She has been chiefly treated for uterine trouble. She does not present any signs of the hysterical temperament. Against hysteria are the facts that, in the first place, she has paralysis of the muscles supplied by the facial nerve; second, she has contracture on the left side, which is sometimes present in old cases of facial paralysis; and, third, the persistence of the condition for fourteen years.

DR. EDWARD T. REICHERT thought that it is not only probable that sweat centres exist in the spinal cord, but also that there is a dominant centre in the medulla oblongata. The latter is no doubt bilateral, and while it generally acts as an individual centre, affecting in like degree sweating on both sides, the centre on one side only may be in a condition of over-excitement, as is probably the condition in the present case, thus causing unilateral sweating. The lesion must, he thinks, be above the middle of the pons in order that there may be paralysis of the face and limbs at the same time.

DR. FRANCIS DERCUM believed that the supposition of some lesion of the cortex going on slowly and leaving a sclerotic patch and followed by degeneration involving these so-called sweat centres might explain the case. As regards unilateral sweating, he observed it for four or five years in a case which subsequently terminated in apoplexy. No autopsy was made.

DR. CHARLES K. MILLS said that Dr. Reichert's remarks would indicate a possible cause for this case. It seemed to him that it might be due to a very small tumor or patch of degeneration of some kind high up in the pons. He found, in looking up the subject, one case of unilateral sweating reported in which degeneration of one of the cervical ganglia was found. He attached but little importance to this. He had recently looked up the subject of unilateral progressive facial atrophy, of which more than fifty cases have now been reported. In a majority of these there has been diminution or entire absence of sweat on the atrophic side.

THE BALTIMORE ACADEMY OF MEDICINE.

Stated Meeting, May 18, 1886.

DR. J. J. CHISOLM read a very interesting paper upon

A COMPLETE REVOLUTION IN THE AFTER-TREATMENT OF CATARACT OPERATIONS.

The method had been suggested to him by Dr. Michel, of St. Louis, whom he had seen at the last meeting of the American Medical Association. It was brought before the Section on Ophthalmology, but did not meet with their approval.

Dr. Chisolm, however, decided to make a trial of the plan suggested, and his results have been so favorable that he has now discarded entirely the old method of bandaging and incarceration of the patient in a dark room, for the new method of simply closing the eye in its natural position and retaining it so by a bit of light adhesive plaster, and allowing the patient the liberty of lighted rooms. The advantages claimed are, first, that a more uniform pressure can be obtained through the natural muscularity of the lids than by any artificial padding that might be employed; and, second, that patients who have not been shut out from the light are less sensitive to its action when the eye is sufficiently healed to permit of its exposure, than those who have been retained in darkened rooms. Moreover, it admits of a means of entertainment for the patient, for they can then have their friends read to them, a privilege denied patients treated under the old plan.

The new method recommends itself especially because it possesses, in a most limited degree, any procedure that alters, to a great extent, the normal relations of the patient. The method in detail is simply this, after the removal of a cataract, or the performance of an iridectomy, the eyes, if a cataract, the eye, if an iridectomy, is closed in its normal position, and a bit of isinglass plaster, about two and a half inches long by one inch wide, rendered flaccid by immersion in some germicide fluid, is neatly applied to the surface of the closed lids. When dried this forms a close, firm band. The patient is then allowed the full liberty of his room, and in every case thus far operated upon the results have been uniformly good.

He has treated eighteen cases (fourteen cataracts and four iridectomies) in this way, and many of them go out from the hospital into direct daylight without even as much as smoked glasses to protect them, and they complain of no photophobia or lachrymation. On the sixth day, when the plaster is removed, the eye stands the light better than it did on the tenth day under the old method. The length of time required for complete healing of the eye operated upon is on an average about two weeks, but the most of the eighteen cases could have left the hospital on the tenth day.

The following officers were then elected for the ensuing year:

President.—Dr. P. C. Williams.
Vice-President.—Dr. Alan P. Smith.
Treasurer.—Dr. G. Lane Taneyhill.
Secretary.—Dr. C. C. Bombaugh.

CORRESPONDENCE.

ERROR IN STATEMENT OF RESULTS OF BATTEY'S AND TAIT'S OPERATIONS. DR. BATTEY CORRECTED.

To the Editor of THE MEDICAL NEWS.

SIR: I am sorry that I have, inadvertently, as Dr. Battey says, stated that Dr. Battey's first case had a fatal result. That the mistake was a slip of the pen, or a mistake in dictating to my secretary, is certain, be-

cause, at page 326 of my book on *Diseases of the Ovaries* (4th edition, 1883), I say: "Dr. Battey, of Rome, Ga., successfully operated upon a patient suffering from serious and complicated symptoms. Dr. Battey was the first to publish his proceedings in the *Atlanta Medical Journal* (September, 1872), whilst I contented myself with discussing the principles only in my Hasting's essay on *Diseases of the Ovary* (published in 1873, but written in 1872)."

Dr. Battey has, in turn, done me an injustice which is probably due to a lack of recollection on his part of what took place whilst he was my guest here from July 27 till August 3, 1881, and also what took place at the meeting of the International Medical Congress in London, on August 5th, of the same year.

On the morning of August 2, 1881, I drove Dr. Battey to see a patient from whom I had removed a small ovary for obstinate and intense pain on February 11, 1872, and I brought from a distance of forty miles the patient whom he says died after the operation on August 1, 1872, in order that he might see for himself the object of this strange mistake, and of the first successful operation for removal of the uterine appendages for the treatment of bleeding myoma.

At the meeting of the International Medical Congress, on August 5th, when Dr. Battey read his paper, I distributed a list of all the cases I had done up to the 14th of July, 1881, and I enclose now a copy of that list from the same bundle as those distributed (to the number of two hundred and fifty) in the room. Dr. Battey had a copy of that list.

At the meeting I specially drew attention to Case H. on the list, because it had by error been published as a fatal case in the *British Medical Journal* for 1879, and I explained how the strange mistake had occurred—a kind of mistake which certainly no one could be accused of making intentionally. I need not say that I was surprised, therefore, when Dr. Battey's paper came to be published, a few months after, that he should not have made the correction which he knew was to be justified, and which he ought to have made. Although he had himself seen and questioned the living patient nine years after her operation, and I remember well he satisfied himself of the complete arrest of menstruation as an immediate result of the operation; his paper said: "August 1, 1872, Lawson Tait practised it at Birmingham with a fatal result." Dr. Marion Sims saw the patient at the same time, and, I think, so did Dr. Briggs, of Nashville, and Dr. Roselmyl, of Hamilton.

Finally, Dr. Battey is wholly in error when he says that my voice was not heard from September, 1872, to May, 1879, on this subject. My first utterance will be found, as I say, in my Hasting's essay, published in 1873, and delivered under seal a long time before its publication, and in my own neighborhood and elsewhere I advocated the removal of the uterine appendages for actual disease, but not for the reflex conditions advocated by Dr. Battey. Battey's operation I did not do till August 11, 1879, and now I do not do it at all. On August 2, 1881, Dr. Battey saw me operate for hydrosalpinx—I think the first case he ever saw. But between 1872 and 1878 were perilous times. The clamp in ovariotomy kept us in terror with a mortality of 25 per cent., and no advance was possible. As soon as we were freed from this we went ahead freely, and now the mortality of all our abdominal operations, hysterectomy alone excepted, has practically vanished.

Priority, after all, is an issue perfectly immaterial, but the mixing up of the principles advocated by Dr. Battey and those advocated by myself as belonging to the same operation, is an error against which I shall never cease to protest.

I am, etc.,

LAWSON TAIT.

BIRMINGHAM, June, 1886.

RECTAL EXPRESSION.

To the Editor of THE MEDICAL NEWS.

SIR: I see in THE MEDICAL NEWS of May 15, 1886, a note concerning my method of rectal expression. I fully realize that all the methods of protection of the perineum during the exit of the fœtal head possess disadvantages, and I do not attach very great importance to the choice of means in such cases. An experienced and observing practitioner may obtain good results by very different methods. I believe, however, that the method of rectal expression is useful in general in primiparæ, and always in cases of delivery by forceps. My own experience leads me to affirm this, and several of my colleagues are of the same opinion.

The objects of the procedure in question are: 1. To render the natural efforts regular. 2. To prevent the rupture of the perineum by a too violent effort during uterine contraction; for the method of rectal expression is peculiar, in that it should be applied in the *interval between two pains*—that is, in the period of absolute passivity on the part of the woman. The tissues are at this time relaxed, and the expression of the head may then be effected without roughness. It is true that the accoucheur in no wise augments, by this procedure, the dimensions of the vulvar opening, but the result is due to the pressure exerted upon the face from below upward, which prevents the abrupt deflection of the head. Neither to me nor to other authors who have previously advised the method does it appear doubtful that it presents marked advantages. The artificial diminution of the cephalic diameters which present at the vulvar orifice is practically the equivalent of proportionally augmenting the area of this orifice.

I agree entirely with the statement in your editorial article that art should imitate nature; but I should be greatly embarrassed to find a method which obeys this precept in the matter at present under discussion. You will agree that it is not imitating nature to retard the progress of the head through the vagino-vulvar canal; yet, nevertheless, both you and I apply and advise this general method. Indeed, nature destroys many perineums. I hope to publish shortly interesting statistics of the results of natural labor, unaided by any artificial means whatever, and I hope to show that rupture of the perineum is, in this case, of great frequency. You are possibly of opinion that nature troubles herself very little about these accidents, which, in effect, assure an easy expulsion in future labors. I, too, would be of this opinion, were the ruptures always moderate; but they are, at times, very considerable.

Again, one must admit that if nature permits spontaneous perineal rupture, she also aids in its spontaneous repair. This is very true, and if it were not needful to take into account the complications which frequently

prevent such repair, I should most willingly leave it to nature, who has done the damage. In the Maternity Hospital, however, this plan of action would be out of place, as, indeed, it would be in city practice. I believe, however, that the method of rectal expression, preceded by a period of waiting such as I have indicated, is a procedure which should not be advised until one is satisfied there is none better. There lies the whole question. I have not pretended to teach a perfect prophylactic procedure, but I believe, after much experimental comparison, that it is, thus far, the best. Believe me, etc., A. Doléris.

Paris, 74 Rue de Miromesnil.

NEWS ITEMS.

Suit Against a Health Officer.—A suit has been begun in the Supreme Court, by William Lockwood and Emory McClintock, rag importers of New York, against Edward B. Bartlett, Albert C. Woodruff, Henry E. Ritchie, and Health Officer William M. Smith, to recover $15,000 damages for losses sustained by the seizure of 3070 bales of rags consigned to the plaintiffs, which arrived at New York on the "Vigilant" and the "Battaglia," on May 30, 1885. The suit is a test case and is extremely important, inasmuch as if it is decided against the defendants other suits will probably be begun to secure to other importers indemnity for the losses suffered by them through the decision of Dr. Smith, that rags from foreign ports must be subjected to the patented process of so-called disinfection controlled by Messrs. Bartlett, Woodruff, and Ritchie.

Physical Training in American Colleges.—The U. S. Bureau of Education has just published, under this title, an elaborate report of 183 pages, on American gymnastic methods and facilities, illustrated by plans of the gymnasiums of the various colleges and universities. The report was prepared by E. M. Hartwell, M.D., of the Johns Hopkins University.

The Pasteur Institute.—The Municipal Council of Paris has placed at the disposition of the Pasteur Institute 2500 metres of land.

Gambetta's Brain.—At the last session of the French Anthropological Society MM. Mattias-Duval and Schudzinsky presented a model of the brain of Gambetta. The region of Broca was seen to be enormously developed, and presented more intricated subconvolutions than have hitherto been noted.

Another Medical Knight.—The honor of knighthood has been conferred on Dr. A. Douglas Maclagan, Professor of Medical Jurisprudence and of Public Health, and Emeritus Professor of Clinical Medicine at the University of Edinburgh.

A Suggestive Method of Averting Ophthalmia.—The Hon. Ralph Abercrombie, in *Nature*, says:

"Three cases have come under my personal observation in which brown-skinned natives, in very different parts of the world, blacken their faces to protect them from intense light and heat." The examples he gives are those of the inhabitants of Morocco, as well as of others along the north of Africa, who blacken themselves around the eyes to avert ophthalmia from the glare of hot sand. The natives of Fiji do the same, and so do the natives of the Sikhim Hills, and it is only reasonable to suppose that a practice of such wide diffusion and such striking similarity is found protective in the places and under the conditions contemplated.

A Sanitary Convention at Coldwater, Michigan, under the auspices of the State Board of Health, will be held on Thursday and Friday, September 23 and 24, 1886.

Lead-poisoning by Household Utensils.—The German Parliament has now under consideration a bill that is intended to regulate the employment of lead in the manufacture of cooking and other domestic utensils, and so to diminish the risk of poisoning by that metal. The provisions of this measure forbid the use of vessels containing more than ten per cent. of lead in their composition for the above purposes. No alloy with over one per cent. may be used in coating iron articles used in cookery. Solder may consist of lead to one-tenth of its amount, but no more. Enamels into which lead enters are treated with equal stringency. The effect of this bill, if it be passed, will be to obliterate the legal existence of pewter and of soft solder as at present made, since these alloys contain from one-half to one-fourth their weight of lead.

Sal Alembroth: Sir Joseph Lister's Latest Antiseptic.—It may be news to a great many to learn that Lister has discarded the use of the spray almost entirely. He now uses sal alembroth exclusively in his wards for dressings, and it has so far given very fine results. It is a double mercurial salt formed by the sublimation of a mixture of perchloride of mercury and chloride of ammonium, and is exceedingly soluble. The salt was known to the alchemists, but has not been used in medicine in modern times. Lister prepares all his dressing now with a 1:100 solution of this, gauze cotton-wool, lint, bandages, draw sheets, and where the wound is covered by the shirt, it is rendered aseptic by dipping it in the solution and drying before the fire. To make any of these dressings, all that is necessary is to soak them in this solution and dry. It not being volatile, does not require to be kept sealed in tin cases. He also colors these dressings with aniline blue 1:10,000, the benefit to be derived from this is that wherever an alkaline discharge comes in contact with the dressing, the blue is removed and turned reddish, enabling one at once to see where the discharge has been, if the quantity was ever so small and had dried up before the dressing was removed. There is one precaution in using this dressing, and that is this: the dressing being dry and frequently handled might have some septic matter from bedclothes, hands, etc., so he always dips it in 1:2000 perchloride just before applying it. He is making a sal alembroth protective, which will be surcharged with the antiseptic, so that as a discharge comes through a dressing it will come in contact with this protective and can be kept aseptic.—*Canadian Practitioner*, May, 1886.

Mistakes in School Architecture.—The *Sanitary News* of March 27th contains an article under the above heading, from which the following notes are taken.

Members of the county boards of health, and others who have at heart the good health of the children of the State, will do well to give these suggestions their attention.

The school building should never be more than two stories and basement high. The ceiling of an ordinary schoolroom should be from thirteen to fourteen feet high. The lighting of the room should be ample, the window-space never less than one-fourth of the floor-space. Lighting from two sides should be from left and rear, but never left and right. The walls are best of some delicate tint. The old-time white wall is irritating to the eye. A hard surface which can be easily washed is to be recommended. The room should be about thirty-two feet long and about twenty-six feet wide. Forty pupils are enough for one room, and the number should never exceed fifty. The floor should be of hard, polished wood, which absorbs little, and is easily cleaned. The above proportions would give each pupil at least twenty square feet of floor space and three hundred cubic feet of air space. The ventilation should be perfect. It should be near the floor. Each pupil should be supplied with 2000 cubic feet per hour, and certainly not less than 1500. With a large number of pupils in one room, this can only be effected by some mechanical means—best by a central ventilating shaft heated by the smoke-stack and connected with the rooms by flues. Earth or dry closets should be used, thoroughly deodorized and frequently emptied.

A Sign of Death.—M. Lessenne, at a meeting of the Société Médicale d'Amiens, pointed out the following simple and trustworthy sign of death. After pricking the skin with a needle the puncture remains open, just as when a piece of leather is pricked. On the living body, even if the blood does not come to the surface, as would happen if the person were hysterical, the pin-prick closes at once, and does not leave the slightest trace.

Inoculation for Yellow Fever.—The modern expedient for settling knotty points in science is to appoint a commission; success, it is true, has not uniformly attended this method, and the reports, if not polemical, are generally colorless. Yellow fever is the disease which is now to be investigated in this way. A few years ago, Dr. Domingos Freire announced that he had prepared a vaccine which preserved the vaccinated from yellow fever; his method of experimenting, however, did not commend itself to bacteriologists; and M. Rebourgeon, who had been trained in M. Pasteur's laboratory, was sent out to Rio de Janeiro to guide Dr. Freire into the right way. The papers since published by these two experimenters confirm the earlier claims, and M. Rebourgeon has returned to Paris to convince the sceptics; he informed the Société de Biologie at its meeting on May 22d, that, during the recent epidemic, 6000 persons had been inoculated, of whom not one suffered from the disease; and that, in seven cases where patients were inoculated while suffering from the disease, recovery took place in every instance. The Society appointed a Commission of five, including MM. Brown-Séquard and Cornil, to study the method.

In the United States, moreover, the demand for a commission has been backed by the American Medical Association.

NOTES AND QUERIES.

THE COPPER TEST FOR SUGAR—A CORRECTION.

To the Editor of The Medical News.

Sir: The abstract published in your issue of June 26, p. 715, of my paper read before the Association of American Physicians, contains an error which, I fear, will give an erroneous impression unless corrected. The reporter says: "Since Dr. Tyson has ceased using copper salts in testing the urine of gouty patients for sugar, he has ceased to find evidences of it." He should have said: "Since Dr. Tyson has been aware that uric acid very frequently reduces the salts of copper, he has not found sugar in the urine of gouty patients," meaning that with proper precautions this source of error is avoided. I still find the copper test, in the shape of Fehling's solution, the most delicate and satisfactory test for sugar.

James Tyson.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING JUNE 26, 1886.

Beardsley, Grove S., *Medical Inspector.*—Detached from the Navy Yard, Norfolk, and ordered to the "Brooklyn."

Bright, G. A., *Surgeon.*—Detached from "Brooklyn," and ordered to Navy Yard, Norfolk.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM JUNE 22 TO JUNE 28, 1886.

McParlin, Thos. A., *Colonel and Surgeon.*—Granted leave of absence for two months, with permission to apply for an extension of one month.—*S. O. 146, A. G. O.*, June 25, 1886.

Magruder, D. L., *Lieutenant-Colonel and Surgeon.*—Granted leave of absence for two months, to take effect on or about July 1, 1886.—*S. O. 146, A. G. O.*, June 25, 1886.

Page, Charles, *Lieutenant-Colonel and Surgeon.*—Leave of absence extended ten days.—*S. O. 146, A. G. O.*, June 25, 1886.

Brooke, John, *Major and Surgeon.*—Ordered for duty as Post Surgeon, Fort McHenry, Baltimore, Md.—*S. O. 67, Division of the Atlantic*, June 23, 1886.

De Witt, Calvin, *Major and Surgeon.*—Ordered for duty in Department of Dakota—*S. O. 142, A. G. O.*, June 21, 1886.

Gardiner, John de B. W., *Captain and Assistant Surgeon.*—Ordered for duty as Post Surgeon, Newport Barracks, Newport, Ky.—*S. O. 67, Division of the Atlantic*, June 23, 1886.

Gibson, Robert J., *Captain and Assistant Surgeon.*—Granted leave of absence for thirty-five days.—*S. O. 43, Division of the Pacific*, June 14, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING JUNE 26, 1886.

Sawtelle, H. W., *Surgeon.*—To proceed to Wilmington, California, on special duty, June 22, 1886.

Wheeler, W. A., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, June 23, 1886.

Williams, L. L., *Assistant Surgeon.*—To proceed to Buffalo, New York, for temporary duty, June 24, 1886.

Norman, Seaton, *Assistant Surgeon.*—To proceed to Cleveland, Ohio, for temporary duty, June 26, 1886.

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course, not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1008 Walnut Street, Philadelphia.*

VOL. XLIX. SATURDAY, JULY 10, 1886. No. 2.

ORIGINAL LECTURES.

THE FREQUENT DEPENDENCE OF DISEASE OF THE EAR UPON CATARRHAL DISEASE OF THE NOSE.

The Annual Address delivered before the Lehigh Valley Medical Association, at Glen Summit, Pa., June 16, 1886.

BY CHARLES H. BURNETT, A.M., M.D.,
PROFESSOR OF OTOLOGY IN THE PHILADELPHIA POLYCLINIC.

THERE have come under my observation so many cases of hardness of hearing in which the throat has been considered the starting-point of the aural disease, and in which the nares, though manifestly the real seat of the original disease, have not been even examined, that my interest in such cases has been especially enlisted. Since aural disease caused purely by throat affections is rarely, if ever, seen, and since all catarrhal diseases of the middle ear, whether acute or chronic, are caused by, or closely associated with, nasal disease, I have proposed to speak to you at this time upon the important causal relation between rhinitis and aural diseases. And, if I succeed in directing your attention to the nares, rather than to the throat, as the seat of the original cause of most cases of catarrhal deafness, I shall be amply rewarded. For I shall feel that I have rendered you a service, if I succeed in disabusing your minds of the erroneous and misleading idea that from the fauces catarrhal ear-disease usually springs. It requires but a little reflection, upon the anatomy and physiology of the nasal cavities, the nasopharynx, the Eustachian tubes, and the middle ears, to see how this should be so. These parts are in intimate relation, both anatomically and physiologically; whereas the fauces and the larynx are connected with the pulmonary system, and their diseases go downward to the lungs, rather than upward to the ears.

It is, therefore, to the structure, and then to an important disease of the nasal and naso-pharyngo-aural mucous membrane, that I especially call your attention. In the nasal cavities there can be distinguished a thick mucous membrane, rich in glands, from a thinner portion, poor in glands, found in the sinuses, on the under surface of the turbinated bones, and in the middle ear. Hence at some places in the nares, like the borders of the cartilaginous septum, and on the inferior turbinated bones, the diameter of the mucous membrane may amount to from 2–4.5 mm. Here the thickness of the mucous membrane does not depend, however, solely on glandular and submucous tissue, but also upon numerous, almost cavernous venous plexuses, or sinuses, especially developed at the edge and posterior extremity of the inferior turbinated bones. These sinuses extend from the interior of the structure outward, so that there is thus formed a kind of erectile tissue at these points in the nose—a most cardinal consideration in the study and treatment of naso-aural disease.

Immediately behind the nasal cavities are found the nasopharynx and Eustachian tubes. The latter may be considered, practically, continuations of the nasal cavities. The mucous membrane of the Eustachian tubes possesses a ciliated epithelium like that of the nasal cavities, especially in the upper and osseous part of the tube.[1] In the lower part of the Eustachian tube, the mucous membrane is richly studded with acinous glands, and it is also thrown into peculiar folds, which are intimately connected with the mechanism of the tube. An inflammation of these districts, therefore, becomes a serious disease, difficult to treat. In the nasopharynx is found, in addition to mucous membrane, rich also in glands and folds of membrane, the peculiar adenoid structure known as the pharyngeal tonsil. These tissues are all more or less erectile, and are extremely liable to be affected by an inflammation in the nares. When these tissues in the nasopharynx and the Eustachian tubes are congested and inflamed, the normal ventilation of the nasopharynx, the Eustachian tube, and middle ear, is impeded, and incipient ear disease, with deafness, is imminent.

Mechanism of the Eustachian Tube.—The Eustachian tube is one-third an osseous canal and two-thirds musculo-cartilaginous, but is lined throughout with mucous membrane. The osseous portion is nearest the tympanum, while the muscular part is in the nasopharynx. A transverse section of the tube in its lower or muscular part shows that its posterior wall is composed of cartilage, and its anterior or lateral wall of muscular and fibrous tissue. The posterior wall curves upward and forward, so that its transverse section is shaped like a shepherd's crook. This wall is firmly fixed to the base of the skull. The anterior or membranous wall is found to give attachment to the fibres of the tensor palati muscle, and is movable. A transverse section of this tube is also somewhat crook-shaped like that of the cartilaginous wall. The part of the lumen under the crook is very narrow but is always patulous from the rigidity of the cartilage which forms its boundaries, and thus constitutes the so-called "safety-tube" of Rüdinger, because, being thus ever patulous, it permits a quick recoil of air from the tympanic cavity. This prevents rupture of the membrana when it is forced inward by any sudden condensation of air or an explosive force, in or about the external ear.

The lower and by far the major part of the calibre of the tube is below the hook in the cartilaginous wall. It resembles, in a state of rest, a mere chink between the cartilaginous and muscular walls, the sides of which are studded with glands, and the mucous membrane of which is thrown into folds. These latter features are especially marked in the parts near the nasopharynx.

[1] It must also be borne in mind that the nerves of the Eustachian tube are derived chiefly from the tympanic and pharyngeal plexus, and that its vascular supply comes from the tympanic and pharyngeal vessels.

The Eustachian tube is opened by the separation of the anterior wall from the posterior. This is effected chiefly by the action of the tensor and levator palati muscles. For, at each elevation and tension of the velum palati, the anterior wall of the tube is drawn away from the posterior wall and the entire lumen is thus rendered momentarily patulous, and the air from the nares and nasopharynx aërates the drum-cavity.

The function of the Eustachian tube is, at each act of swallowing, to supply air to the tympanic cavity, and thus maintain an equilibrium in the air-pressure on each side of the membrana tympani. This holds the membrana and the chain of ossicles in a state of isolation, as physicists term it, and ready for proper, pendulum-like oscillation, or vibrations, upon which hearing depends. If the membrana is not thus maintained in a state of equilibrium as to the pressure of air on either side, the membrane yields to the greater pressure on one side, and sinks inward or bulges outward according to the direction of greater pressure. In the first state, that of retraction, the chain of bonelets is locked, their joints are held too tight, they cannot vibrate freely and hearing is impaired at once. When the membrane bulges outward, it draws the malleus away from the incus, the normal medium of auditory vibrations is thus disturbed and hearing is altered. The first state, that of retraction of the membrane and locking of the chain of bonelets, may occur in acute coryza and in other catarrhal processes involving the nasopharynx, because the mucous membrane in the nasopharynx and about the mouth of the Eustachian tube is swollen so as to impede the proper opening of the tube, and the ventilation of the tympanic cavity. In chronic catarrhal processes the disease of the mucous tissues may become so great as to extend to the underlying muscular tissues and there induce a form of paresis which renders the muscles inefficient in a ready opening of the Eustachian tube, and normal airing of the tympanic cavity. It is easily seen, therefore, how important an inflammation in the naso-pharyngo-aural mucous membrane becomes. Such an inflammation has received the name of catarrh, or catarrh in the head. In our language the term catarrh is limited, in the present day, almost entirely to inflammation of a subacute or chronic form, in the nares and naso-pharyngo-Eustachian mucous tissues.

The symptoms of ordinary acute coryza are too well known to require enumeration or close description here. There are, however, some reflex nervous symptoms and aural phenomena connected causally with coryza and rhinitis which demand our attention. These, with their treatment, should receive due regard from every practitioner of medicine, because upon their prompt recognition and proper treatment often depends the function of hearing. The duration of the symptoms of acute rhinitis varies from three or four days to as many weeks, although after lasting the latter period it may begin to assume a chronic form. The voice assumes the nasal twang when the anterior nares are chiefly affected; when the posterior nares are the chief seat of swelling, *m* is pronounced as *b*, and *n* as *d*. Then, too, the Eustachian tube is more or less involved in the swelling of the mucous membrane, and its permeability is impaired, as shown by the tinnitus aurium, the altered quality of sounds, or decided hardness of hearing. If the sinuses are implicated, there is pain in them; or if the middle turbinated bones are pressed upon (Allen), there may be a pain in the temporal or parietal region, or even in the vertex. When such a grade of catarrhal swelling has invaded the nasopharynx and the nares, there may be dull and fugitive pains in the ears, which may settle into constant earache when relief is not given to the closed tympanic cavity. In infants the symptoms are often serious, as they cannot suck, on account of their closed nares, and their ears may become either the seat of acute inflammation, inducing convulsions, or the Eustachian tubes may become chronically closed, producing deaf-dumbness.

An excitation of the nasal mucous membrane induces reflex phenomena—*e. g.*, lachrymation, copious secretion of nasal mucus, reflex cough, disturbed respiration and phonation, asthma, spasm of the larynx, and spasmodic aphonia. It is also claimed by some that epilepsy may be evoked by chronic nasal irritation. It is a fact that congestion of the membrana tympani, and of the anterior wall of the external auditory canal near the membrana, and dull earache, are produced by acute rhinitis. These are purely reflex phenomena in many instances, being due to diminished inhibitory power in the vasomotor nerves of this region. Vessel dilatation and passive congestion, passing often into inflammation, are the results. It was once supposed that inflammation of the ear in rhinitis was due to direct extension of inflammation from the nares, through the Eustachian tube to the middle ear. This may, indeed, occur; but sometimes the external surface of the membrana and the external auditory canal alone are found inflamed in acute coryza, the Eustachian tube and middle ear remaining intact. The path of nervous connection in such cases is through the nasal branches of the sphenoid palatine ganglion, and thence by the sympathetic connection with the carotid plexus to the vessels supplied by the carotid to the membrana tympani, and those parts of the external auditory canal near it.

Predisposing causes of acute rhinitis are childhood and the strumous diathesis, in which the tonsils, the nasopharynx, and the Eustachian tube are likely to be affected. Also those who lead a sedentary life, the rheumatic, those with feeble respiratory systems, and the nervous, are prone to nasal catarrh.

The exciting cause is usually exposure to cold, though exposure to the heat of the sun, and confinement in hot apartments, may also induce an acute coryza. According to Morell Mackenzie, coryza occurs epidemically "only when a sudden lowering of the temperature coincides with an increased humidity of the air." There is no evidence that acute coryza is infectious, and the experiments of Friedreich on inoculation upon himself were negative in their result.

No less an authority than the late Cohnheim, said: "The essence of inflammation is not to be found in either the dilatation of the vessels, in the increased rapidity of the flow of the blood, or in the subsequent contraction of the vessels, but in some unexplained local change in the walls of the vessels of the part affected." What this change is, he was not able to say, as he had not succeeded in finding any structural alteration. Nevertheless, discussion of the etiology of coryza and of the *modus operandi* of the alterations produced by chronic catarrh in the upper air-tract, seems

desirable. While indisposed to ascribe catarrh of the nares to cold entirely, yet I confess to belonging to that part of the profession which believes that a change of temperature, most usually an influx of colder air upon the mucous membrane of the nares and fauces, and upon the general surface, in what may be termed an unprepared state, causes acute rhinitis, or a cold in the head.

As soon as inflammation has set in, in such a tract, exposed as it is in a high degree to the atmosphere, I can easily see how it is that germs are found in the results of inflammation very soon in the course of the disease; but these are emphatically *post hoc* and not *propter hoc*, in their occurrence. They appear because a fitting soil for germ growth is then supplied by the inflamed mucous membrane and the morbid and decomposing secretions.

An example of such occurrence of germs and mycelial development after irritation and inflammation of living tissue, is seen in the growth of aspergillus in the auditory canal and over the membrana tympani. Here the irritation and abrasion of the skin tissues come first, according to my observation, either from undue efforts of the patient at scratching or cleansing the meatus, or from a furuncle. A little serum or blood is thus exposed to the saprophyte, it settles on the already wounded tissue, and grows. The inflammation is usually increased by the growth of the parasite, but it is most surely not caused by it. So in catarrh of the nares; the germs described as causative in this disease are most probably the result of the lodgement of germs, always to be found in the atmosphere, and hence easily brought to the air-passages, where, in the catarrhal state, is furnished a soil favorable to the full development of a so-called specific disease-germ.

Were this not so, all the so-called prodromes of coryza must be held to be sequences of the lodgement of "coryza germs" in the nares, their invasion of the submucous tissues, and of their development therein: which no one is quite ready to assume. It may, however, be admitted that a specific germ may specifically aggravate an inflammatory process already established in the nasal mucous membrane, but until it can be shown that it is the entrance of such a germ into the nares which inclines the skin to become chilled and the nasal mucous membrane to become congested, it cannot be said that the germ produces coryza. At certain times, and in some conditions of the atmosphere, there may be an excessive number of irritating germs in the air we breathe, and at such times a coryza may be more easily contracted, or, if already existing, may be made worse.

Coryza is, in reality, due to inflammation of the part of the body offering, as it is aptly termed, the "least resistance" at the time of exposure to changes of temperature.

The theory of "least resistance," to which I adhere, is somewhat like this, as set forth by Niemeyer: At a given time there is a certain quantity of blood in the body, evenly diffused throughout the vascular tract. If a contraction or congestion take place at any point in this tract, an over-distention must ensue in some other part as a compensation. This causes a congestion in the compensating region. Thus, after extensive burns of the skin, inflammation may ensue in the bowels. It is claimed that, like all fluids, the blood, when compressed at any point, will seek a recoil at the point of least resistance, and thus, in the instances alluded to, certain parts far from the original irritation are congested, and even profoundly and fatally inflamed.

It is further claimed that the mucous membrane of the respiratory tract is more liable to be congested than other parts of the body, because it is rarely ever free from irritation by foreign substances, especially in so-called civilized communities. Dust acts as an irritant, and the impure air of houses, factories, schools, etc., lowers the tone of the capillaries of the respiratory tract, and renders them still more liable to inflammations. Thus, when the temperature of the surface of the body is unduly or suddenly lowered, the upper respiratory tract, especially the nasal cavities, becomes easily and quickly congested and inflamed, and we say we have "taken cold."

If the attacks of coryza, or "cold in the head," become numerous; if the patient begins to take cold easily, as it is termed, the nares, the point of least resistance in such a case, soon become chronically engorged and a tendency to chronic nasal and aural catarrh is developed.

The Nares in Infants.—In the nasal cavities in infants the meatuses are very narrow, and the free edge of the inferior turbinated bone is longer and curved further around into the meatus so that there is scarcely any passage.[1] The relative smallness is most marked in the middle meatus. Infants in health breathe naturally through their nares, which obviates mouth-breathing and favors a healthy condition of the nasopharynx and Eustachian tube. But the natural smallness of the nasal meatuses favors their easy closure by a swelling of their mucous membrane, such as a coryza would induce.

This liability to a greatly stopped nose in infants favors the development of chronic nasal catarrh of the hypertrophic form, closure of the Eustachian tube, and chronic catarrh of the middle ear, with profound hardness of hearing. This condition in infants is most disastrous, as it tends to make them deaf-mutes. It is thus, without doubt, that many cases of so-called congenital deaf-dumbness are brought about, the deafness being in fact due to a neglected, because unrecognized chronic hypertrophic nasopharyngeal catarrh occurring soon after birth. The process is similar to that in an adult, but more intense and more rapid, and occurring at a time when the child must hear in order to learn to talk, the deafness interferes with this acquisition and the sufferer becomes a mute. I have seen cases in which there was a clear history of such a catarrhal process in the first year of life, and no history of any other malady to account for the deafness. Congenital deafness is most rare; it is indeed very doubtful whether it ever occurs, excepting in an otherwise malformed child. In all cases of so-called congenital deafness, unless there is a distinct history of a traumatic or febrile cause, I have found that the undoubted cause has been a chronic and neglected rhinitis, ending in chronic catarrhal otitis media. The hyperplastic tendency being great at this age, the deafness soon becomes profound and permanent. The lesion at first is most probably occlusion of the Eustachian tube and ankylosis of the chain of ossi-

[1] Kohts and Lorent, 1878.

cles. Finally there is degeneration of the nerve filaments in the labyrinth. The prognosis is, of course, most unfavorable, unless the disease is recognized and treated at the beginning.

Earache in Children.—Acute coryza in children is especially likely to produce congestion of the vascular and glandular mucous membrane of the nares and nasopharynx, closure of the Eustachian tube, mouth-breathing, and earache. This does not always produce rupture of the drum membrane. The state of congestion seen in these cases seems to intermit in daytime, nose-breathing gets easier, mouth-breathing less frequent, and the earache may pass off, so that the child plays around the house, or even goes to school or plays in the open air. If, however, the membrana tympani be examined, it will be found that it does not lose its congestion, but remains red and macerated or infiltrated in appearance. As night comes on, the nares and nasopharynx become more congested and the ear begins to ache again. This catarrhal otitis may continue for several days without any more severe symptoms than I have given. On the other hand, the symptoms may suddenly grow worse, the patient may have a continuous and severe pain in the ear with an intensity of suffering which is relieved at last by a rupture of the membrane and the escape of muco-pus from its tympanic cavity. In infants, such a tympanic inflammation, resulting from a coryza, may induce convulsions, or even meningitis and death, without the discovery of the true aural origin of the disease. In such an instance the convulsions and brain disease are attributed erroneously to teething, that great scapegoat, which is supposed to produce diarrhœa in summer-time, and coryza in winter-time.

The results of inflammation in the nares and nasopharynx are easily divided into the acute and the chronic. The acute inflammation soon passes on to exudation, the exudate consisting of the blood-plasma with leucocytes. Generally, however, after such an acute inflammation, the mucous membrane returns to its normal condition. At all stages of a catarrh, however, there is a swelling of the mucous membrane which leads to obstruction of the nares and other passages connected with them, all of which are temporary in acute forms. In the chronic forms a permanent thickening of mucous membrane in the nose, Eustachian tube, and middle ear ensues.

In adults, and also in some children, the earlier and simplest effect of a cold in the head, upon the ears and the hearing, is a slight stuffed sensation in one or both ears, with subjective buzzing, singing, or pulsating sounds in the ear, and, in some instances, an alteration in one's own voice and in the hearing. This may be at first a hyperæsthesia, or it may be a slight impairment in the auditory sense. These symptoms may all pass away as the nares get clearer, without any treatment. But these simpler phenomena, in and about the Eustachian tube and middle ear, may become intensified. The stuffed feeling may increase, itching and pain may pass from the back part of the nares into the ear, and an acute otitis media catarrhalis may be developed, with decided impairment of hearing.

These phenomena may also gradually subside by a form of resolution, in the course of three or four days or a week, leaving at most a stuffed and crackling sensation from the hypersecretion in the Eustachian tube and the middle ear. Gradually these products may be absorbed, the tissues may reassume their normal tenuity, the hearing may be reëstablished, and the attack forgotten, without any special treatment.

Frequently, however, the catarrhal congestion and closure of the Eustachian tube do not terminate by this fortunate resolution, but all the symptoms grow worse; there is earache, and there is developed an acute purulent inflammation of the middle ear. These cases generally terminate by a perforation of the membrana tympani, an escape of muco-purulent matter and pus from the tympanic cavity by the way of the external meatus of the canal, and for the time being, at least, there is hardness of hearing. Such a process may involve both ears, though usually only one ear is affected in this manner by an acute coryza.

The Chronic Form.—The surgeon now begins, in the observation of such a case of aural inflammation, to approach the chronic results of catarrhal processes in the nares and nasopharynx. For after a perforation of the membrana and the appearance of a purulent discharge, the disease loses its acute form and assumes more or less chronicity. It will be found that a similar chronicity or subacuteness has been assumed by the disease of the nasal and nasopharyngeal tissues. The medical attendant is now called upon to investigate most thoroughly the condition of the inflamed parts, and to treat them as will be shown later.

I have thus sketched the course of a catarrhal process in the nares and middle ear, which has ended in suppuration and the destruction of tissue. There are, however, *more* cases in which the catarrhal process in the nares and nasopharynx tends to a thickening of the tissues in the nares, Eustachian tube, and middle ear than to suppuration and destruction of tissue.

These are the true chronic catarrhal processes, assuming from the outset a tendency to chronicity, appearing with every cold, getting a little worse with each such attack, or with some other constitutional malady, and finally gliding into truly chronic nasal and aural catarrh, with more or less profound deafness. These are hypertrophic processes, to begin with, in which there is a tendency to the formation of hypertrophy in the nasal mucous membrane, especially on the turbinated bones and in the Eustachian tube. Such a process in the naso-Eustachian tract leads to thickening of the mucous membrane in the drum cavity, and to retraction of the membrana tympani. Their onset is often insidious, without the fulminant attack of the purulent form, which, if properly managed, usually terminates favorably in every way.

The chronic catarrhal process, with the hypertrophic tendency, however, often attracts little or no attention at first. It is noted that colds in the head, or in the nasopharynx, make the ears dull of hearing in the early attacks. This dulness does not pass off readily, but gets worse, and remains longer after each coryza. Finally, the hardness of hearing becomes permanent, either with or without tinnitus aurium, and in one or in both ears. Usually both ears are affected in chronic hypertrophic catarrh, but not to the same extent.

The impaired permeability of the Eustachian tube and the imperfect ventilation of the tympanic cavity, induced by catarrhal swelling in the mucous membrane of the nasopharynx and Eustachian tube, brings about

a diminished aëration of the drum cavity. The air in this cavity not being renewed with normal frequency, or not at all, as in some cases of profound swelling of the mucous membrane, the air locked in the drum cavity is soon absorbed and a quasi vacuum formed. The external air now forces the membrana tympani inward, the ossicles are carried with it, and tinnitus aurium, deafness, and vertigo are caused.

Vertigo, more or less pronounced, may occur in both acute and chronic naso-aural catarrh. It is generally worse, however, in the latter than in the acute condition. It is due to pressure upon the endolymph in the vestibule and other parts of the labyrinth, and thence upon the cerebro-spinal fluid. This pressure is exerted by the forcing inward of the stapes in the oval window, by the retracted membrana tympani as already stated, and also by the direct pressure of the swollen mucous membrane of the drum cavity, upon the membrane of the round window. By the force arising from these sources the endolymph is compressed and the terminal filaments of the auditory nerve, especially those portions in the ampullæ of the semicircular canals, are compressed. By this means the so-called vertiginous centre of the brain is irritated, and the patient experiences vertigo, with reeling and vomiting, and, in some cases, syncope. The latter, however, is rarely observed, and then only after intense and prolonged nausea. One of the guiding points in the differential diagnosis between aural vertigo and vertigo from cerebral disease, is the retention of consciousness in aural vertigo, notwithstanding many epileptiform accompaniments.

Treatment.—Having shown that disease of the nares and nasopharynx is the original cause of most aural disease, treatment must necessarily be directed to these parts. A word must also be said here about the prevention of disease in the nares and ears, as well as concerning the diet and general hygiene in colds in the head and ears. Cold water must not be allowed to enter the external ear of any one with a tendency to aural inflammation, and snuffing water into the nares, for purposes of cleansing or hardening the tissues and keeping off colds, must also be prohibited. If cold water enters the external ear, myringitis and even otitis media may be the result in any one, whether predisposed especially to catarrh or not. Water snuffed into the nares can be drawn easily into the Eustachian tube and the middle ear, and thus otitis media acuta, with intense suffering, induced. After any form of bathing the head, the hair and scalp should be dried as thoroughly as possible. After such ablution, draughts at all seasons of the year, and even going soon into the open air in the winter-time, should be avoided. If in spite of all precautions, coryza is contracted and the nasopharynx and the ears become affected, the first care should be to protect the body by housing, and the treatment may be briefly defined as diaphoretic and antiphlogistic. The diet should be plain and light. There is no more fallacious aphorism in popular medicine than "to feed a cold." Highly seasoned food and spirituous drinks quickly congest the fauces, nasopharynx, and ears, and, therefore, must be avoided. Smoking by the mouth, but not by the nares, may be indulged in if desired. Parenthetically, it may be stated that the practice of smoking through the nose is very likely to induce, in anyone, nasal catarrh and aural disease. In winter time, or in cool weather at any point in the calendar, it will be safest for the patient to remain in the same room, with a uniform temperature of not less than 70° F. At other seasons this matter must be decided by convenience and the patient's feeling.

The patient's mind must be disabused of the idea, so widespread in the community, of "breaking the cold" with quinine. Next to the high-feeding fallacy, in the treatment of colds in the head, comes the quinine treatment, largely carried on by patients themselves. Upon the slightest intimation of the onset of an acute rhinitis or "a cold," they prescribe for themselves and their friends ten grains or even twenty grains of quinine at a dose. This congests the auditory canal and the membrana tympani, as revealed by inspection, and tends to congest the head generally, and, of course, the patient is not only made more uncomfortable, but he runs the risk of inducing by his rash therapeutics a profound congestion, and a permanent lesion in his cochlea and auditory nerve.

The recent experiments of Kirchner, Schilling, and Schwabach, with quinine and salicylate of soda, show that large doses of these drugs may produce destructive changes in the labyrinth and auditory nerve contained therein. The lesion has been shown by post-mortem examination of the ear of cats to consist in a copious extravasation of white and red blood-corpuscles throughout the cochlea and other parts of the labyrinth. Hence, caution is necessary in administering this drug where congestion about the head and ears is already established.

Quinine judiciously administered at the termination of the acute symptoms of a coryza will tend to overcome the debility which invariably attends this disease, but in the acute stages I do not hesitate to say it is contraindicated, unless in very small doses of four to six grains daily, to overcome an unusual prostration.

The sudorific and anodyne treatment can be best carried out by the use of Dover's powder, the bromides, hamamelis, gelsemium, and aconite. If patients will honestly submit to hygiene and treatment at the hands of an educated physician, their colds can generally be shortened and cured. If they will not submit to rational treatment, they, and not their physicians, are to blame. Dover's powder acts better in many cases when given in small doses during the day, rather than at night in one dose. Laudanum in doses of from five to seven drops, several times daily, will also control irritation and lead to its resolution in numerous cases of acute coryza. Benefit may be derived also from vapors of camphor and iodine, and fumes of benzoin. The patient should be cautioned against sneezing, or even blowing the nose forcibly, as both acts tend further to congest the nasopharynx and the Eustachian tubes.

The bromides may be given in small doses, five grains every hour, and two or three grains of chlorate of potash may also be given, as frequently, in the form of lozenges, to be slowly dissolved in the mouth. This treatment, carried out while the patient remains in his room, I have known greatly to curtail the acute stages of a coryza, and to give relief to the peculiar irritation in the mucous air tract, so hard to endure in this stage. It has seemed to me to act by producing free diuresis.

Hamamelis is best exhibited in the form of the dis-

tillate, ten to fifteen drops, three times daily. It is claimed by many to have an aborting power over the congestion in the nares, and, so far as my observation goes, it seems to merit its reputation. Gelsemium and aconite have their best effects in the more febrile and neuralgic forms of coryza, and hence are indicated in such instances. Tincture of gelsemium may be given in doses of five to fifteen grains, according to the age, and aconite in doses of one-tenth of a grain of the extract, every hour, until its effect is noticed.

I would venture to suggest that antipyrin in five grain doses is worthy of trial in the febrile stage of coryza, but a limited experience would prevent my urging it strongly.

The local treatment of the nares and fauces forms an important element in the management of these cases of naso-aural disease, because it is necessary to restore the normal calibre of the nares and Eustachian tubes. Syringing the nares, in all forms, is to be condemned as too irritating and, hence, liable to provoke further disease. Under this head is also to be placed the nasal douche; this may give relief, if properly used, but it is dangerous from the risk incurred by its use, of forcing fluids into the middle ear.[1] The local treatment should consist in sprays from the hand atomizer, and, in some cases, in applications made directly to the nares by a tuft of cotton, on the cotton-holder, under good illumination by the forehead mirror.

It is of the highest importance not to irritate the already excited mucous membrane of the nasopharynx. Its erectile nature and the relation the nasopharyngeal mucous membrane sustains to the Eustachian tube and middle ear, and the ready transmission of disease from the former to the latter must not be forgotten. It has been stated that the Eustachian tube opens at each act of swallowing, and some claim that it is opened at each respiration. The air which enters the tympanic cavity at such times maintains the equilibrium of the membrana and the ossicles. If such aëration of the tympanum stops for even a short time, the ear is quickly placed in the first stage of deafness. The object of the physician should be to prevent this, or, if it ensue, to restore the normal ventilation to the middle ear as soon as possible.

In infants and very young children we must be on the lookout for the effects of chronically stopped nares. For, undoubtedly, chronic aural catarrh and consequent deaf-dumbness, originate in infants from neglect of close observation of, and attention to, the inflamed nasopharynx and middle ears. In many cases this might be prevented by prompt and simple treatment. Mouth-breathing, which tends to induce collapse of the Eustachian tube and membrana tympani, must be corrected. All these early conditions of closure of the Eustachian tube, and the consequent collapse of the membrana in children and adults, can be overcome by some form of aërial inflation of the tympana.

The simplest for all cases and the most efficient for children is Politzer's inflation or some of its modifications, by means of the hand-bag or air-douche as it is sometimes called. In adults the Eustachian catheter can be employed if only one ear is affected, and if it be desired not to inflate the well ear, or if the air-douche fail. Politzer's inflation of the tympana consists in forcing air from a specially arranged air-bag, held in the hand, into the nasopharynx through the patient's nose at the moment of swallowing, for at such a time the nasopharynx is shut off from the fauces, and the Eustachian tubes are drawn open by the elevation of the velum. It can be performed by means of a piece of rubber tubing. In order to insure swallowing at the proper moment, the patient is told to swallow a little water previously taken into his mouth. The same object can be effected in many cases by the simple act of phonation of the broad sound of *a*, or by simply puffing out the cheeks, according to the suggestion of Dr. Holt, of Portland, Maine. If little children cry, the operation is thereby aided by the elevation of their palates. The use of the Eustachian catheter is a matter of too much importance to be described in a short time. None but the specialist is liable to be called upon to use it often, if at all.

Successful inflation of the tympana is a most important and valuable acquirement for the physician, and of great assistance to the patient, for, by this means earache can often be promptly stopped, dulness of hearing overcome, and an attack of extravasation and inflammation in the drum cavity warded off. If vertigo is present, especially in the acute forms of otitis and rhinitis, it can often be entirely relieved by a thorough inflation of the tympana, since by this means the equilibrium of air on each side of the membrane is restored, and the pressure of the foot-plate of the stapes upon the endolymph and arachnoidal fluid is taken off.

The local treatment of the nares in acute and chronic rhinitis is best attained by the use of sprays thrown by the hand atomizer. Thus, in the acute forms, sprays of fluid cosmoline, and of the distillate of witch-hazel, one part to three or four of water, may be employed. In the more chronic or subacute forms, Dobell's solution may be sprayed into the nares, and this followed by spray of fluid cosmoline. The fauces may be touched with a weak solution of tannin and glycerine, or some of the weaker preparations of the Rhus glabrum, or common sumach. I must speak most positively against the use of nitrate of silver in chronic hypertrophic catarrh of the nose and throat. I shall not endeavor to mark out a line of treatment for the chronic forms of rhinitis, when connected with aural disease, as in this stage the general practitioner will often find that he lacks time to cope with them.

In the acute stage great comfort is given to the patient by insufflations of the compound bismuth powder, *e. g.*:

℞.—Morph. sulphat.	. . . .	gr. x.
Sodii bicarb.	. . . .	gr. xv.
Bismuthi subcarb.		
Acaciæ pulv.	. . . .	āā ʒij.

M. and powder most finely.

This may be used in small pinches several times daily in adults, during the most acute stages of coryza. Of course, care must be exercised in its use, both in adults and children, on account of the risk of poisoning by the

[1] If, however, solutions of salt in water are thus thrown into the nares and nasopharynx, they should be what are known as "blood solutions"—*i. e.*, fifty-six grains to the pint in strength. If not, endosmosis or exosmosis is excited in the nares, according to the less or greater strength of the solution.

morphia in it. Solutions of cocaine (four to six per cent.) seem to allay the nasal irritation in severe cases. This may be instilled into the nares, or painted over the turbinated bones with a hair pencil.

If earache is present, these applications to the nares, together with *inflation of the tympana, if done soon*, are often sufficient to allay the suffering by reëstablishing the normal ventilation of the nares, Eustachian tubes, and the middle ears. If this procedure be insufficient for relief of the pain in the ear, and suppuration seem imminent, we have a choice of a number of methods. Dry heat is always better in the treatment of earache than moist heat, as the latter is too macerating and threatens the integrity of the drum. Hence poulticing the ear must be strictly prohibited. Warm water irrigation may be tried, and will often give relief; but it is inconvenient. I have succeeded in allaying earache, due to coryza, by applying in front of the auricle a flat, four-ounce bottle filled with very hot water. Most instillations are dangerous from their liability to irritate the canal and membrana, and hence make matters worse. Laudanum and warm water or warm alcohol are among the most likely to give relief.

If the pain be not very severe, a 10 to 20 per cent. solution of cocaine or 5 per cent. solution of brucia applied in the auditory canal may control it. If the suffering grows intense and a suppurative process threatens, leeching may be resorted to—*i. e.*, one to three large European leeches may be placed *in front* of the tragus or under the lobule, but never in the meatus or in the auditory canal.

It is also claimed by many that $\frac{1}{20}$ to $\frac{1}{10}$ gr. of sulphide of calcium three or four times daily, will control the tendency to suppurate, and therefore, when combined with aconite in small doses ($\frac{1}{10}$ gr. of the extract) three or four times daily, given at the outset of the disorder, will tend to allay the pain of tympanic inflammation. In some cases I have thought I derived aid from this much talked-of anti-suppurative medicine when I have been able to give it at the beginning of the symptoms.

If, notwithstanding all the efforts of the surgeon to mitigate the ear pain and prevent suppuration, the latter ensue, and rupture of the membrana tympani be imminent, paracentesis of the latter should be performed. This will usually relieve the pain at once, give vent to he accumulated muco-pus, and prevent an extensive or an entire sloughing of the membrane. It is to be performed only under perfect illumination of the auditory canal and membrana by the forehead mirror and by an experienced hand. The instrument must be a slender shaft with a delicate needle-like blade, and the most prominent point on the membrane must be chosen for the puncture. This will usually be the lower and posterior quadrant.

After the paracentesis of the membrana there is an escape of pus or muco-pus from the tympanic cavity. The pain now ceases, either immediately or in the course of a few hours, according to the less or greater severity of the inflammation in the mucous membrane of the drum. The discharge usually continues, and would become chronic were it not carefully treated by astringents and antiseptics. In order not to favor suppuration, aqueous solutions are not as valuable as powders. Hence, the dry treatment—*i. e.*, clearing the ear by mopping with absorbent cotton and the insufflation of finely powdered boric acid, is preferable to the moist treatment of otorrhœa by syringing and the instillation of astringent drops. The treatment, furthermore, whatever it be, is more efficacious if carried out by the surgeon rather than by the patient. Hence, the latter may be obliged at first to visit his doctor daily, if his physician cannot go to him. Prompt treatment, therefore, of a "gathering" in the ear will be just as satisfactory as prompt treatment of an abscess elsewhere, and as by the latter procedure sloughing and burrowing are prevented, so in the ear total loss of the membrana and ossicles, with impairment of hearing and an offensive otorrhœa, are obviated by prompt recognition of the nature of the aural disease and a rational treatment of the same.

ORIGINAL ARTICLES.

THE PHYSIOLOGICAL ACTION OF THE HEAVY OIL OF WINE.

BY HOBART AMORY HARE, M.D. (Univ. of Pa.),
PHYSICIAN TO THE CHILDREN'S DISPENSARY OF THE UNIVERSITY HOSPITAL AND TO ST. CLEMENT'S DISPENSARY; ASSISTANT IN PHYSICAL DIAGNOSIS IN THE UNIVERSITY.

The heavy oil of wine, as one of the component parts of Hoffmann's anodyne, occupies a prominent but an unrecognized place in our list of remedies.

According to the U. S. Dispensatory, this agent is formed by the distillation of alcohol with a large excess of sulphuric acid. The product of the distillation is generally in two layers, one of which contains the heavy oil of wine, while the other layer consists of sulphurous acid. For the purpose of separating any ether which may be in the oily layer, it is exposed to the air for twenty-four hours, when it is washed with water, thereby removing any sulphurous acid which may contaminate it, and after these two processes have been accomplished the oil is ready for the market. Notwithstanding the fact that Hoffmann's anodyne is so frequently used, and has for so long a time occupied a prominent place in the household, and a useful one in the profession, curiously enough, nothing seems to have been done toward increasing our knowledge of its composition or of its physiological effects. Its formation is generally accounted for in the following manner:

When sulphuric acid and alcohol are added together, one of the results of their union is sulphovinic acid ($C_2H_5HSO_4$); but if the sulphuric acid be in great excess the sulphovinic acid is partially decomposed, forming the heavy oil of wine.[1] The mixture now consists of ethyl-sulphate, $(C_2H_5)_2SO_4$; ethyl-sulphite, $(C_2H_5)_2SO_3$; and ethyline, C_2H_4. Two forms of this ethyline are known, viz., etherin and etherol, and the mixture of these two separate forms of ethyline alone, forms the *light oil of wine*.

The same doubt seems connected with the specific gravity of the heavy oil. Sadtler believes 1.133 to be the most correct estimation of its specific gravity yet made.

[1] Dr. Squibb believes the heavy oil of wine to be a sulphovinate of a hydrocarbon radical.

At the suggestion of Dr. H. C. Wood, I performed the following experiments in order to discover what part was played by the oil when administered with alcohol and ether in Hoffmann's anodyne. Of course, under the latter circumstances the action of the oil is entirely subservient to and masked by the more rapidly acting and more diffusible stimulants; but the results of the following investigations were, at least, marked enough to show that the drug before us occupies no mean position in the anodyne mixture. Starting with the object of seeing in what manner the circulation is influenced, and beginning with the heart of the frog, the following results arose from my investigations:

When the isolated heart of the frog is placed in the pure oil the rapidity of its movements is increased very distinctly (about ten beats more a minute) for some moments; following this stage of stimulation comes a condition of exhaustion or depression, during which the cardiac movements are imperfectly performed, with a constantly increasing feebleness, and finally the viscus stops in diastolic collapse.

Seven other experiments with the isolated heart now followed, a weaker solution of the oil being used in each experiment, and it became evident that the duration of the period of stimulation was in inverse ratio to the size of the dose, so that the seventh heart had its increased rapidity of movement continued for a longer period than any of its predecessors. The action of the drug when dropped in varying strengths upon the heart when lying in its pericardial sac was identical with its effects upon the isolated viscus, so far as the eye could discern. Unfortunately, any study as to the relative propelling power of the heart when under the influence of the oil was impossible, owing to the fact that no frogs of sufficient size were obtainable; the hearts I was obliged to use being too small for use in any of the so-called frog manometers. It is evident, however, that in small and ordinary quantities the heavy oil of wine is a cardiac stimulant, while overwhelming doses are needed to produce cardiac depression.

12.22.30	.....	170–160	198	Injection ended.
12.22.40	.....	160	194	

The experiments made on the higher animals—the dog, for example—showed that the drug affects the mammalian circulatory system in much the same manner as it does that of the frog. It will be seen from the accompanying table and tracings that small doses of the oil (2 to 7 minims) increase pulse-rate, force, and pressure, while larger doses (1 to 2 c. c.) decrease pressure to a considerable extent; exceedingly large doses seem necessary to depress the heart. Indeed, the perfect vasomotor palsy resulting from large doses of the oil would seem to point to the conclusion that the heart stops rather because its vital centres do not receive a sufficient quantity of fluid for their maintenance, than to a direct depressing action of the drug on that viscus, for it has already been shown that overwhelming doses are necessary to depress the heart of the frog, and one of

TRACING NO. 1.

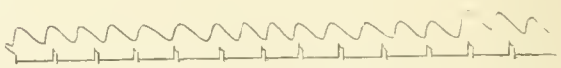
the subjoined tracings shows how much power remains in the heart even when the *arterial pressure* is not more than 5 mm. above the abscissa line.

TRACING NO. 2.



Showing rate and fall of pressure produced by 10 c. c. of the oil injected into jugular. The increased height of the pulse wave over the normal is always present when the vaso-motor system is depressed and the heart is not.

A brief glance at the experiments so far performed shows that this oil produces on the circulation the following effects:

1st. Small doses increase arterial pressure.
2d. Large doses decrease arterial pressure.
3d. Small doses increase rate.
4th. Very large doses are required to diminish rate.
5th. Small doses increase force.
6th. Large doses do not decrease force.
7th. That it requires very large doses, indeed, materially to decrease force.

The questions now arising, limit themselves to the consideration and the elucidation of these results, and each one was examined in the above order and individually.

It was proved, by careful and repeated observation, that the rise in pressure following the administration

of from 2 to 7 minims of the oil was due in no way to a respiratory action of the drug, for in the curarized animal the rise was as great as in the dog, the respiratory functions of which were not interfered with, and there are, therefore, but three modes of explaining this increase of pressure. Either the vasomotor system is stimulated centrically or peripherally, or cardiac force is sufficiently increased to produce a general rise in pressure. As every one knows, this latter condition is scarcely ever met with in an unalloyed state, a vasomotor stimulation generally accompanying increased cardiac force.

Few drugs also produce peripheral vasomotor excitability, without affecting the higher vasomotor centres in the fourth ventricle. It was proved by two experiments in which the spinal cord of a dog was severed high up in the cervical region, thereby causing a complete cutting off of any impulses from the centres, that this rise was due to a centric action of the remedy, probably aided by the cardiac stimulation, for under these circumstances no rise of pressure took place when the drug was given. The decrease in arterial pressure produced by large doses of the drug evidently depends, in great part, on a peripheral as well as a centric action of the oil, for in the dog in which the cord was intact the fall was not as great as in the animal the cord of which was divided. It would, therefore, seem probable that the drug in large doses affects the centres to but a slight extent, for if its dominant action under such circumstances was centric, we should expect to find as great a degree of fall when the cord was intact as when it was cut. The extreme difficulty surrounding all efforts to decide whether the peripheral vasomotor action of a drug is alone the cause of a fall of pressure, prevents our absolute decision on this point. While we cannot, therefore, state that the heavy oil of wine paralyzes the centres or periphery, singly and individually, we can rest assured that it does, in large doses, depress the peripheral ends of the vasomotor nerves. (See tracings numbers 3 and 4.)

TRACING NO. 3.

Cord cut: normal tracing.

In regard to the increase in pulse-rate following small and moderate sized doses of the oil, we find that it is probably due to a direct cardiac stimulation, rather than to any depressing action on the inhibitory nerves. This is pointed to by the fact that the rapidity of movement in the frog's heart when isolated was increased by the drug, and also by the fact that section of these inhibitory nerves invariably caused an increase in rate of so decided a character, that any previous vagal depression could hardly be present. Further than this, other experiments showed that when section of the vagi and cord was

TRACING NO. 4.

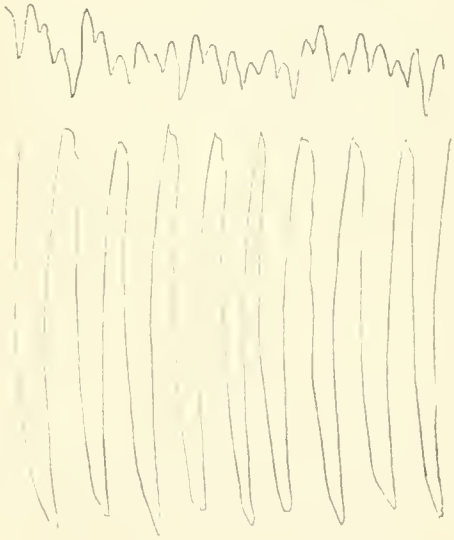
Cord cut: showing complete vasomotor palsy produced by 4½ c. c. of the oil.

synchronously made, thus leaving the heart free from all nervous influences of a centric character, the same increase in rate took place as when the cardiac nervous system was intact.

The decrease in pulse-rate produced by enormous doses of the oil is also due to a direct effect upon the heart itself, for it occurred both when the vagi were cut and when they were whole; the same condition also obtained when the cord was cut. Section of the vagus during the period of decrease in rate caused but a momentary and transient quickening.

When small doses have increased cardiac force, the force is increased by a direct action on the heart muscle or its ganglia; or, in other words, the stimulation which increases rate also increases force. This is rendered the more likely by the fact that cardiac

TRACING NO. 5.

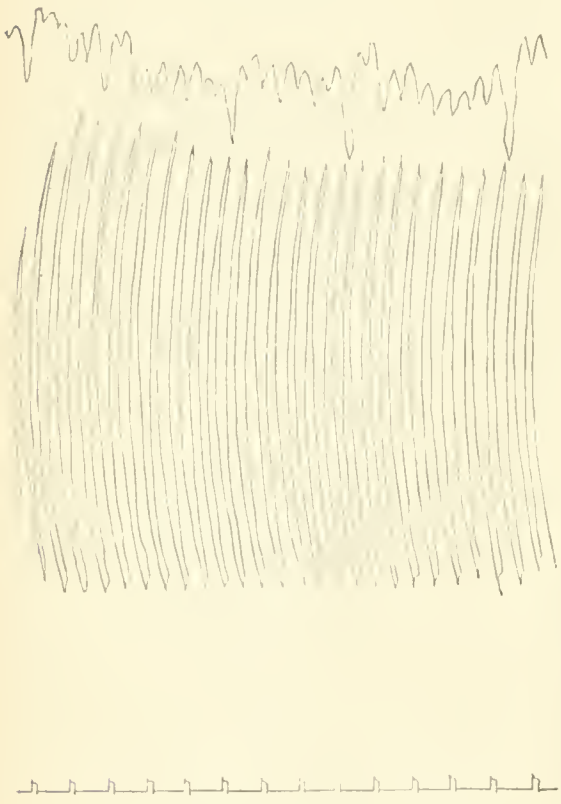


Normal tracing.

force remains almost as long as cardiac rate is increased, or at least until the rapid rate is no longer one of power, but of weakness.

Very large doses cause decrease in heart power by a direct action on the heart muscle, and by producing such a general vasomotor palsy that the heart cannot obtain a sufficient quantity of blood to enable it to drive out through the hungry bloodvessels a fair-sized pulse-wave. The heavy oil of wine in the dose of 3 c. c. to a very strong and powerful dog weighing 25 pounds, increased the force and rapidity of his respirations very markedly, as may be seen from tracings numbers 5 and 6. Violent spasmodic efforts at forcible breathing came on after the administration of a

TRACING NO 6.



Showing increased respiratory rate after 3 c.c. of the oil.

second dose, but as these severe respiratory changes did not occur in other dogs under like circumstances, I believe them to be due to the plugging up of the minute bloodvessels near the respiratory centres by minute oily emboli.

On the nervous system the drug seems to exert but little influence, for even when given in enormous doses to frogs no nervous phenomena were developed, and careful electrical studies on the nerves and muscles when in contact with the oil failed to show any signs of action of the drug.

While the writer was unable to demonstrate any nervous effects produced by the oil of wine, he does not wish it thought that he denies that such influence exists, although he believes it to be very slight indeed. From his experiments it seems probable that

First. The belief in heavy oil of wine being the quieting agent in Hoffmann's anodyne, is fallacious.

Second. That the calmative effects of this mixture depend largely on the ether, rather than on the oil.

Third. It would seem probable that in Hoffmann's anodyne we possess an agent in which there are linked together three drugs of undoubted power, each one of which successively substitutes the other, stimulating the system in the order here named, viz., ether, alcohol, and the heavy oil of wine.

On animal temperature, as ascertained by the thermometer in the rectum, no effect is produced, even when the arterial pressure is very low. That large doses of the heavy oil of wine are in no way possessed of toxic effects, was proved by the fact that 30 c. c. of the drug given by the mouth to a small dog, weighing 12 pounds, failed to produce any apparent symptoms, except, perhaps, to stimulate him slightly. While the odor of the oil is penetrating, it is by no means disagreeable, and it possesses but little taste other than that of the presence of an oily substance.

AN UNUSUAL GUNSHOT WOUND OF THE THORAX.

BY W. T. COUNCILMAN, M.D.,
ASSOCIATE IN PATHOLOGY, JOHNS HOPKINS UNIVERSITY, BALTIMORE.

A FEW weeks ago I was called upon to make an autopsy in which death had resulted from a gunshot wound received under the following circumstances:

Two lads were struggling for the possession of a pistol, one having hold of the barrel of the weapon, the other the handle. The boy holding the barrel gave a sudden jerk, pulling the pistol toward his breast, and the weapon was accidentally fired just at the moment it touched his body. The pistol was an old-fashioned muzzle-loading weapon, with a barrel six inches long, and a calibre of forty-eight. It was loaded with a heavy charge of powder and a slight paper wad. The body was that of a slightly built boy of fourteen, fairly well nourished, and with a rather thin skin.

There was a large gaping wound of the thorax extending from one and a half inches below and to the median line of one nipple to a corresponding point on the other side. The wound was sharp, clean-cut, and had all the appearances of an incised wound, except in the middle, just over the sternum, where both the upper and lower edges were lacerated to a slight extent. There were no powder marks on the skin, the wound was blackened at the point of laceration, and only slightly so elsewhere. The skin was torn loose from its connection over a space six inches in diameter, its internal surface and the torn muscle and fascia blackened and burned with powder.

The sternum was extensively comminuted; there was a transverse fracture across the lower third of the gladiolus, and numerous other longitudinal fractures extending from this. The bone looked as if it had been laid flat and struck with a heavy hammer. The cartilages of the fourth and fifth ribs on either side were torn from their connections with the bone. At the point of the transverse fracture there was an irregular hole in the bone half an inch in diameter. On the internal surface the periosteum was torn from the bone in large shreds and blackened. The anterior surface of the pericardium was torn away, and a large

ragged opening made into the heart. The right auricle and ventricle were laid open, and there was an opening in the interauricular septum half an inch in diameter. The edges of the heart wound were blackened, and in the wound were found small irregular bits of bone, some of which had penetrated into the left auricle. Both pleural cavities were opened, and contained a considerable amount of blood. There was no injury to the lungs or to the posterior pericardium. The diaphragm was intact. There were several ruptures in the left lobe of the liver, two on its upper surface, and five on the lower surface opposite to those on the upper. All of these ruptures extended from one-quarter to a half inch into the parenchyma of the organ. A very slight quantity of blood was found in the abdominal cavity. All of the organs were pale and exsanguine.

When he was shot the boy had on a heavy woollen shirt, in which a ragged orifice with burned edges was found. When shot he uttered a loud cry, made a few steps forward, and fell dead.

In this case it is probable that the great laceration of the skin, and parts beneath, was due to the expansion of the gases of combustion beneath the skin. Most books on medical jurisprudence speak of the fissuring of the skin from pointed projectiles, and from expansion of gas when the weapon is held close to the body. I have not found a case, however, in which the fissure of the skin was so extensive, straight, and sharp, as in this case. The ruptures in the liver show how great the force of concussion must have been. The laceration of the heart was due, in great part, to the pieces of bone which were forced in, but the tearing effect of the explosion evidently made itself felt here also.

REMARKS ON THE VALUE OF ANTIPYRIN IN PUERPERAL FEVER.[1]

BY JOHN BLAKE WHITE, M.D.,
VISITING PHYSICIAN, CHARITY HOSPITAL, NEW YORK.

SERIOUS structural changes are to be dreaded when continued pyrexia obtains in any form of disease, but in none is the danger greater than in puerperal fever. The wet pack, cold sponging, and cold coil, in local inflammatory conditions, are, indeed, valuable means for reducing temperature and allaying inflammation, but they possess features of objection, because of the danger of disturbances to which they often subject the patient.

The effects produced upon the system are, nevertheless, the same as when a high temperature is gradually reduced by internal medication.

The reduction of temperature should be effected gradually, however, if satisfactory and safe results are to follow. A review of the following cases of puerperal fever treated with antipyrin will demonstrate its value in relieving the hyperpyrexia present, and thus contributing to their successful termination.

CASE I.—Mrs. B., aged twenty-eight, primipara, confined May 2, 1885. Labor natural, convalescence advanced satisfactorily until the fifth day, when the patient had a severe chill, followed by fever. Pulse 135, temperature 105°. Severe abdominal pain was complained of, and the patient assumed the prone position with thighs flexed. On examination the abdomen was found tympanitic, the most careful manual investigation producing great pain. The face was flushed and anxious, and the patient complained of severe headache and mental confusion. There was a partial arrest of the lochia and some fetor. The milk secretion was checked; carbolized vaginal douches were ordered. Warm turpentine applications made frequently to the abdomen. Opium to relieve pain prescribed, and fifteen grains of antipyrin given every three hours until three doses were taken. This treatment produced strikingly satisfactory effects, and in due time the patient made a good recovery. As soon as the pyrexia was overcome with the antipyrin, the lochial discharge was fully reestablished, the milk returned, and no unpleasant result whatever followed.

CASE II.—Mrs. D., aged twenty-eight, primipara, confined February 23, 1885. Labor tedious, followed by *inertia uteri* during the second stage. Labor was terminated with the forceps. Patient progressed favorably until the fourth day, when she was seized with a severe chill, followed by high fever and peritonitis. This condition modified both the milk secretion and the lochial discharge, the latter emitting fetor. The same general treatment was carried out as in the preceding case. Antipyrin was given in the same dose at regular intervals of three hours until the fever was controlled, and in due time a most satisfactory convalescence was the result.

CASE III.—Mrs. J., aged twenty-four, multipara, confined March 29, 1885. Labor natural. Convalescence progressed until the sixth day, when late at night I was hastily summoned and found the patient delirious with a temperature of 105.2° and pulse proportionately rapid, skin hot and dry. Abdomen tympanitic, lochia arrested and milk suppressed.

Opium was given to relieve pain, hot turpentine stupes applied to the abdomen, carbolized douches ordered, and antipyrin gr. xv administered every two hours until three doses were taken. The temperature declined under the treatment. For several days the fever returned with the other threatening symptoms, which were as readily combated with the antipyrin as at first. As soon as the fever declined in each instance the lochia returned, and the secretion of milk was reestablished, after which convalescence progressed satisfactorily.

CASE IV.—A case of measles complicating puerperal fever. Mrs. W., aged twenty-four, primipara, confined June 4, 1885. Labor natural. Convalescence progressed until the fourth day, when severe abdominal pain was complained of, preceded by a rigor. When the patient was seen the abdomen was hot, intumescent, and tympanitic; the patient's position was symptomatic, reclining on the back with thighs flexed and body bent forward. The expression was anxious, face flushed, respiration painful, headache intense. She complained of severe sacro-lumbar pain and retention of urine. The temperature was 104.5° and the pulse 140. Respirations were not counted, but were rapid and shallow in character. The lochial discharge was suppressed and the secretion of milk also arrested. Hot turpentine stupes were directed to be frequently applied to the abdomen until some relief from pain was experienced. Opium was given in appropriate doses. Carbolized vaginal douches were ordered and antipyrin administered in gr. xv doses every two hours until three powders were taken. My next visit was made soon after the third powder was administered, and the temperature was found reduced to 102°, with every other symptom less urgent.

Fifth day: Temp. 101°; pulse 100. The patient's condition was in every respect more satisfactory. She still

[1] Read before the Manhattan Medical and Surgical Society.

experienced some pelvic pains, and the opium was accordingly continued at longer intervals. The lochia were partially restored and the milk secretion was renewed. The antipyrin was given in the same dose once every five hours and vaginal douches continued.

The patient was favorably progressing up to the eighth day, when I was hastily summoned and found symptoms of peritonitis again pronounced. The temperature ranged as high as 105°, and the pulse was correspondingly rapid. I suspected her guilty of imprudence, and soon learned that the patient had been persuaded by a friend to get up and exert herself in order to "encourage her strength."

Although I had cautioned against such imprudence, when my back was turned the patient had yielded to other advice with the result stated. This second seizure very nearly proved fatal. All of the dangerous symptoms returned to an alarming degree. The same treatment already detailed was carried out and antipyrin again administered as before. On the following (9th day) the temperature was 99.5°, the pulse 100, and every condition of the patient improved. On the 10th day the bowels were moved by an enema and convalescence seemed assured. I would have had, in all probability, no further trouble with the case but for the following unfortunate occurrence.

The patient's sister came from Philadelphia to be present during the confinement, and brought her little son, who was taken ill at this juncture with a pretty severe attack of measles, requiring his mother's constant attention. My patient would not consent to her sister's returning home while the child was so ill, and I, of course, advised against his being exposed to the danger of so long a journey in that condition. Although isolation was as studiously practised as possible, the contagion nevertheless found its way to the sick-room, and the puerperal woman was taken ill with the measles. The temperature increased to 105°, and when the eruption appeared it manifested itself profusely over the face, trunk, and extremities. The usual catarrhal symptoms were pronounced, and the paroxysms of coughing caused severe abdominal and thoracic pains. The pulse was quite rapid, face very much flushed, and the patient's general condition seemed so critical that I became very anxious of the result.

Antipyrin was again administered as before with striking effect. The temperature and pulse readily declined. The next morning the patient's condition appeared less grave. Antipyrin, however, was continued night and morning in doses of gr. xv throughout the pyretic period, and appeared to exert a wonderful antipyretic influence. The infant was also taken ill with the measles, but made as good a recovery as the mother.

I have had the same satisfactory results follow after using this drug in other cases of like character, but these instances have been selected for report as characteristic cases, and are sufficient to prove the value of antipyrin in puerperal fever, as well as to place it among the most safe and useful antipyretic remedies in all fevers.

I have had no reason to think that the remedy exerts any direct influence upon the uterus by which the lochial discharge is restored when suppressed, but it has seemed that this good result was effected secondarily through the reduction of the high temperature which is always present in these cases. It appears to me that the pyrexia in puerperal fever checks involution, and an arrest of the lochia follows. The discharge becomes reëstablished upon the reduction of temperature brought about, I think, by the sedative effect of antipyrin upon the circulation, and its effect upon the vasomotor system, dilates the capillaries and modifies or removes local congestion.

I admit the difficulty of determining as yet how the antipyrin acts, but it cannot be doubted that it exercises a bradycrote influence upon the circulatory system. Dujardin-Beaumetz thinks the toxic effect of antipyrin the same as that of resorcine or carbolic acid, though less manifest than in the two latter drugs. He says that it produces, in overdoses, tetanic and paralytic symptoms, analogous to those caused by strychnine, and declares that it cannot be doubted that the drug acts upon the cerebro-spinal axis and probably lowers temperature by effecting a modifying influence on the nervous heat centres. Or, does the remedy enter the blood and arrest fermentative processes excited therein by a specific fever germ, and thus control high temperatures?

Antipyrin is a product of destructive coal tar distillation, and is chemically known as *dimethyloxychinine*, approaching quinine in composition, but possessing a far less bitter taste and more positive antipyretic effects. The preparations of tar which have been heretofore used medicinally, are well known to exercise a controlling effect upon fermentation existing along the digestive tract. Dangerous collapse has been attributed to the drug, but I have witnessed no ill effects from its use, though I have frequently prescribed it in many fever cases. From the fact, however, that overpowering collapse has been said to threaten when it is employed with digitalis, I am inclined to believe that its action is also that of a cardiac and circulatory sedative. It does certainly reduce the force and frequency of the heart's action, which may explain the condition of collapse supervening when these remedies have been combined in prescription. As it does not seem to be cumulative in its effects, no accident, so far as I know, has followed the use of antipyrin prescribed alone and in appropriate doses at regular intervals, as already stated.

My experience with the remedy, in both hospital and private practice, in the treatment of many fever cases, has taught me that it should not be combined with any remedy which acts as a sedative upon the circulatory organs. Doses of fifteen grains or twenty grains, repeated in one, two, or three hours, *pro re nata*, appear to be the only safe way in which to prescribe it. I have seldom found it necessary to give more than three or four doses of the amount cited, and this repeated at such stated intervals is found to reduce the temperature effectually and sometimes permanently from 105° to 100° or less. If fever should recur, this dose continued once or twice daily until convalescence is advanced, will prove a useful adjunct to other treatment.

Since the preparation of this paper, I have read with much interest an article by Dr. A. A. Smith,[1] in which he bears testimony to the value of antipyrin, "as the most useful and safest antipyretic yet discovered if used in not too large doses, and if in connection with its use cardiac stimulants be given when there is any suspicion of cardiac enfeeblement."

The only cases in which I have found it necessary

[1] Medical Record, Feb. 27, 1886, p. 238.

to combine any stimulant with antipyrin, have been such as would have demanded stimulation under ordinary circumstances, from the debility consequent on the affection itself, and not because of any depressing influence incident to the employment of the drug.

941 Madison Avenue, New York City.

MEDICAL PROGRESS.

Bacteriotherapy of Phthisis Pulmonalis.—Dr. Ballagi has carefully followed the bacteriotherapeutic details advised by Cantani in eight cases of advanced phthisis with moderate fever; many bacilli in the sputa. During the inhalations the sputa were daily examined for bacilli and bacterium termo. The following results were noted:

1. In none of the eight patients was a diminution of the bacilli demonstrable.

2. Fever, cough, and other symptoms were as troublesome during the four or five weeks in which the inhalations were given as before.

3. No arrest or regression of the phthisical process was at any time demonstrable by physical examination.

4. In one patient diarrhœa occurred, which ceased only upon stopping the inhalations.

5. After ten to fourteen days the patients strongly objected to the inhalations, and only four held out beyond four or five weeks. The nauseating smell and taste of the (freshly prepared) solution of bacterium termo decreased appetite, and the weight of patients also decreased somewhat.—*Centralb. f. d. gesammte Therapie*, May, 1886.

The Bronchial Secretion as an Absorbent.—In January last, Dr. B. W. Richardson, while suffering from a bronchial cold, accompanied with rather free secretion from the bronchial surface, discovered on the morning of the 18th that the secretion had a peculiar and fetid odor. He detected this first in the pocket handkerchief he was using, and surmised at first that the odor might by some accident have come from it, although it was quite clean. He therefore obtained another handkerchief which certainly had no odor, but the result was the same whenever the bronchial secretion came in contact with it. Fresh cotton-wool receiving the secretion had also the bad odor imparted to it. He would have felt anxious but for the circumstance that he recognized the odor of some decomposing animal matter which he had detected on the table of the laboratory on the preceding day when at work there. He sought, therefore, for the offending cause, and found it in a Leyden jar, which contained a portion of the brain of a sheep that had undergone decomposition, and that had not been removed. He closed the jar, took a carriage drive into the suburbs of London, indulged in a good brisk walk, and returning home, found the expectoration free of all fetor. The next morning, the expectoration being still free of fetor, he reopened the jar, and breathing near it for a short time, found that the secretion was rapidly reinfected, and that it was just as easy to communicate the odor to the expectoration as it was to the moist hand, to moistened cotton-wool, or to a watery solution of albumen.

This little observation seems to be of moment as explaining the mode in which some infections are directly communicated. When we consider the large area of the bronchial surface, and its position in relation to the blood, we can easily see how the whole volume of the blood may be poisoned from prolonged inhalation of air charged with putrid matter. The observation is also useful in showing how quickly fresh air, even near a large city, removes the danger. It may be that in some diseases affecting the nasal organs and upper part of the throat, the great benefit which so often accrues from even a few days' change into pure air at the seaside, may be due to the deodorizing effects of the air on nasal and bronchial secretions in a state of partial decomposition.—*The Asclepiad*, April 25, 1886.

Climacteric Diabetes in Women.—In an article with this title Lawson Tait says: Roughly speaking, the conclusions that I have arrived at concerning this affection are that in the great majority of cases of eczema of the vulva at the climacteric period, the disease is due to the presence of sugar in the urine. I have not yet come across a case of this kind in which, having examined for sugar, I have not found it. The disease seems to begin at or near the arrest of the menstrual functions, and to extend over a period of several years, then terminating in all probability by nature's own process. The sufferings of the patient are very much diminished, and probably the duration of the disease is shortened, by the liberal administration of opium, whilst the local trouble is best mitigated by ointments containing such substances as will arrest the process of fermentative change in sugar. So far, the best substance that I have found for the purpose is the old-fashioned hepar sulphuris.—*The Practitioner*, June, 1886.

A Study of the Senile Testicle.—In an inaugural thesis thus entitled, M. H. G. Arthand presents the following conclusions:

1. At about the age of fifty years the human testicle is subject to a gradual regression which induces atrophy.

2. This atrophy is characterized by a marked pericanalicular sclerosis and by the disappearance of the epithelial element.

3. As a result of the sclerosis there appear atrophy of the seminiferous tubules, varicose dilatation of the ducts of the epididyma, and later, the formation of cystic cavities.

4. The sclerosis and its accessory phenomena may be regarded as the result of vascular lesions and of the insufficient nutrition of the seminal glands in advanced age.—*Annales des Maladies des Organes Génito-Urinaires*, May, 1886.

Nature and Cause of Internal Rotation.—Dr. D. Berry Hart thus formulates a law governing the internal rotation of the fœtus:

1. Whatever part of the fœtal head or trunk first strikes a lateral half or lateral part of the sacral segment is rotated internally to the front, and in the direction opposite to the lateral half or lateral part of the segment so acting.

2. No part of the fœtus is ever rotated directly into the hollow of the sacrum. The passage of the occiput into the hollow of the sacrum in its so-called posterior rotation is exactly equivalent to the passage of the sinciput into the hollow of the sacrum in normal rotation,

and should be excluded from descriptive terminology, as the latter is.

3. The direction of rotation may be predicted in any case by noting what part first strikes a lateral half of the sacral segment.

This view of rotation gives, in my opinion, a more coherent idea of all the rotations than those based on the shape of the head or pelvis only. I do not deny the influence of the shape of the internal surface of the pelvis, but I deny that it alone can determine rotation.

It seems to me, also, that we here see an explanation of the pelvic inclination, Roederer obliquity, Solayres obliquity, and general shape of head and body of fœtus.

The pelvic inclination, as we term it, gives us, by its slope, a short anterior pelvic wall, and may be looked on as due to a slicing away, as it were, of part of the anterior pelvic wall. The kidney shape of the brim, such that the head there does not fully occupy it, and lies with the Solayres' obliquity, is necessary for the distention of the bladder during pregnancy; while the shape of the occiput, chin, neck, and sternum allows of Roederer's obliquity in head cases, or extension in face cases, so as to make a part, either occiput or chin, usually lead during labor. The short anterior pelvic wall and oblique and deep position of a part of the fœtus (occiput, chin, breech) bring necessarily the fœtal part lying anteriorly at the brim early within the reach of a lateral portion of the sacral segment—*i. e.*, tend to cause its early rotation.—*Edinburgh Medical Journal*, May, 1886.

Nitrite of Amyl in Whooping-cough.—At a recent meeting of the Philadelphia Neurological Society, Dr. Morris Lewis stated that he had exhibited nitrite of amyl with advantage in a case of whooping-cough. The drug was diluted with three times its bulk of ether, and the finger, wetted with the mixture, held before the child's nostrils at the first respiratory effort. The frequency of the paroxysms was not lessened, but their severity and the attending exhaustion were greatly diminished. In the discussion Dr. H. A. Hare stated that he had once checked a paroxysm of whooping-cough by this method, and that it did not return for twelve hours, although prior to this the attacks had been of hourly recurrence.

Researches on the Biological Action of Silver.—Curci (*La Medicina Contemp.*, March, 1886) has experimented with a double hyposulphite of sodium and silver, this salt being very soluble, not coagulating albumen, non-irritant, and readily absorbable by the subcutaneous connective tissue. In frogs, silver paralyzes the excitomotor nerve apparatus of the heart, and in this way produces slowing and progressive weakening of the systole and arrest in diastole. It does not paralyze the muscular fibre. In mammals, silver acts on the bulbar vasomotor centre, at first stimulating it and therefore increasing the arterial pressure, then paralyzing it and lowering the pressure. It causes the peripheral arterial vessels to contract, but has no action on the veins. It acts on the nerves and excitomotor ganglia of the heart, gradually paralyzing them, causing the heart to become flaccid, the pulse weaker and smaller, and finally paralyzing it. The paralysis of the central vasomotor nervous system, and particularly of the pulmonary vasomotor fibres, aided, perhaps, by the cardiac paralysis, is the cause of the congestion and œdema of the lungs. Therapeutically, silver, owing to its power of diminishing and abolishing the excitability of the sensory, cerebral, and spinal nerve centres, is rationally indicated in epilepsy, locomotor ataxy, and other diseases of the great nervous centres, characterized by increased excitability. From its action on the respiratory centre, it is useful in nervous or idiopathic asthma. Since it also diminishes and abolishes the excitability of the ganglia and excitomotor nerves of the heart, it is useful in some cases of angina pectoris. It probably also calms the morbid excitability of the aortic and cardiac plexuses of the sympathetic. Curci recommends that the internal use of the nitrate should be abandoned, since in contact with the mucous membrane it is rapidly altered, and may cause the dark discoloration known as argyria, and this without its true action on the nervous system ever being obtained. He recommends instead the double hyposulphite of sodium and silver, which is very soluble in water, is not caustic, does not coagulate the albuminoids, is very diffusible and promptly absorbed by the mucous membrane and subcutaneous connective tissue. Its taste is sweet and slightly nauseous; it should be given fasting or hypodermatically. The dose by the mouth is from five to twenty centigrammes, daily, or one to five centigrammes hypodermatically. Its action on the nervous system is surely and quickly obtained, and the danger of argyria is avoided.—*London Medical Record*, May 15, 1886.

Preliminary Note on the Microbe of Rabies.—G. F. Dowdeswell writes as follows in the *Lancet* for June 12, 1886:

In view of the great interest now taken in this subject in consequence of the brilliant investigations of Pasteur, I think it desirable to take an early opportunity of stating that I have found the microbe which appears closely to constitute the virus of this disease. It is a micrococcus, not very minute, and of the usual form. It stains, however, with some difficulty; and this accounts for its having hitherto escaped observation. In the cases of dogs which I have as yet examined, its principal seat is evidently the central canal of the spinal column and spinal oblongata; thence it pervades the other tissues of the central nervous system, occurring (sometimes in vast masses) around the walls of the bloodvessels, and in some cases within the vessels amongst the red blood-corpuscles. In the cortex of the hemispheres I have found it, but in very small numbers, and, so far, only in the perivascular and pericellular lymph spaces. In the cerebellum I have not found it at all, neither have I as yet succeeded in finding it in the salivary glands. I shall shortly publish the methods by which it may be stained with certainty. I must, however, state that it does not stain by hæmatoxylin, either with or without a mordant, as asserted by Fol.[1] I have repeated his methods carefully. Neither does it occur within the nerve fibres, as he states; and, lastly, it is fully three times the dimensions which he gives. I may add that it does not occur in the same situation, treated by the same methods, in normal animals. In the one case of

[1] Comptes Rendus, Dec. 14, 1885, vol. cl. p. 1276.

a rabid dog, which I had examined to control my previous observations, the tissues were placed in alcohol so shortly after death as to preclude the possibility of the occurrence of septic organisms. In addition to which, all saprophytes, so far as yet observed, stain very readily with the usual aniline dyes, which this microbe does not. I must point out, in justice to the genius of Pasteur, that these observations on the occurrence of the microbe go far to confirm his statement of the seat of the virus; it may further afford a means of diagnosis in any doubtful case.

Treatment of Ciliary Eczema.—Hébra commends the following ointment, as applied morning and evening to the free edges of the eyelids in ciliary eczema:

Lead plaster,	
Olive oil	āā 10 parts.
Balsam of Peru	1 part.

Massoin, who cites the prescription, states that in the same affection advantageous use may be made of a one per cent. solution of benzoic acid, with which the eyes are to be frequently washed. The vehicle advised is plantain water.—*Revue de Thérapeutique*, April 15, 1886.

The Fluorides of Ammonia and Iron.—Dr. John Lucas, of Bombay, has employed the fluoride of ammonia in the treatment of hypertrophy of the spleen.

The drug appears to have antipyretic and antiperiodic properties, as proved in cases of ague. Nausea was produced at first, but afterward large doses could be borne. The appetite, after a time, improves under its use. By giving the drug after meals its nauseant and purgative actions are greatly lessened. "It certainly appears to possess the merit of excelling any other method of treatment of hypertrophied spleen with which we are acquainted." Dr. Lucas began with five-minim doses, but in future would be disposed to give twenty, or even thirty, minims well diluted. The fluoride of iron would, perhaps, be preferable to the ammonia salt, on account of its hæmatinic properties.—*The Lancet*, May 22, 1886.

Diphtheria Not a Sewer-Gas Disease.—Dr. Erwin F. Smith, in a paper on the "Influence of Sewerage Water-supply on the Death-rate in Cities" (Report of Michigan State Board of Health, 1885), makes the following statements with regard to diphtheria and sewerage.

1. Diphtheria is as frequent in the country as in the city—*i. e.*, in non-sewered as in sewered districts.

2. Diphtheria has been more frequent and fatal in certain rural districts than in any city whatsoever.

3. Diphtheria is not more frequent or fatal in sewered cities than in unsewered ones.

4. Of two given cities, equally well- or ill-sewered, diphtheria, during a long series of years, may be widely prevalent in one and rare in the other.

5. Certain sewered cities have never suffered seriously from diphtheria, while others have been afflicted very much worse in recent years (*i. e.*, since the houses have been protected from sewer air), than formerly, when, with the same sewers, but much less perfect plumbing, flushing, and ventilation, the sewer-air found its way into a majority of the houses.

6. When an epidemic of diphtheria appears in a city, the sewered and unsewered portions generally suffer alike.

7. No relation of interdependence can be traced between diphtheria and the sanitary state of a city, such, for example, as enables us to predict with almost absolute certainty, the typhoid fever mortality of a city from a knowledge of its sanitary condition, or conversely, the sanitary condition from its typhoid mortality.

8. The annual mortality from diphtheria fluctuates greatly, and this, too, in cities where the sanitary conditions are very nearly constant.

9. Diphtheria is a disease of cold weather, being most active when putrefactive decomposition in sewers is presumably least so.

10. Diphtheria is a contagious disease, transmissible from person to person and place to place, like smallpox and scarlet fever.

11. The closing of schools and other places of public gathering checks an epidemic; and the isolation of the sick from the well, with the subsequent proper disinfection of the sick-room and its contents, extinguishes it.

12. The data relied upon to prove a connection between sewerage and diphtheria, either cover too short a period to be trustworthy, or are drawn from single cities having incomplete and defective sewerage.—*The Medical Age*, May 10, 1886.

Duration of Vitality in Cholera Bacilli.—Guttmann and Neumann send from the Bacteriological Institute of the Moabit Hospital of Berlin, the following brief but important communication:

They have kept cultures of cholera bacilli in agar-agar for two hundred and eighteen days, and similar cultures in the beef-extract, peptone, and gelatine mixture for two hundred and nineteen days. At the expiration of these periods respectively, the bacilli were found capable of transplantation and continued development, and also produced their characteristic effects upon inoculation in guinea-pigs.—*Centralb. f. klin. Med.*, May 1, 1886.

Treatment of Vesical Calculi.—Dr. N. P. Dandridge, in a paper read before the Ohio State Medical Society, in June, 1886, thus formulates his experience in the treatment of stone.

Every case demands

1. An examination of the urethra, to determine its calibre and its tolerance of instruments.

2. A careful estimate of the size and composition of the stone.

3. A careful examination of the urine, to determine the character of the stone and the presence of Bright's disease or diabetes.

The present aspect of the treatment of vesical calculi justifies, in his opinion, the following conclusions:

1. In children, all cases should be submitted to lateral lithotomy, except in the very rare cases where the size of the stone demands the high operation.

2. In adult cases rapid lithotrity should be the rule, and is capable of dealing with about nine-tenths of all the cases met with.

3. Stones of unusual size, from one and one-half ounces upward, should be submitted to suprapubic lithotomy.

4. Stones formed round a foreign body can be safely removed by median lithotomy, even when of large size.

5. Stricture, simple and uncomplicated, should first be relieved by dilatation or internal urethrotomy, and the stone subsequently crushed.

6. Stricture, when indurated, or complicated by fistula or marked cystitis, should be submitted to a perineal lithotomy, and, by preference, the median operation should be chosen.

7. In hypertrophy of the prostate, the question of operation is to be largely determined by the necessity for drainage of the bladder.

8. The same can be said of the influence of cystitis in deciding upon the choice of operation.

9. In case of uncertain diagnosis, the median operation is indicated in order to permit of digital exploration of the bladder cavity.—*The Cincinnati Lancet-Clinic*, June 5, 1886.

Treatment of Syncope in Adolescents.—Dr. Clement Dukes, Physician to Rugby School, writes as follows to the *Lancet* of May 8, 1886:

An adolescent was sent to me with the statement that he had nearly fainted on three different days, but he did not become insensible. He came with the request that I would ascertain the cause of his faintness. Cases of the kind have happened to me under similar circumstances so many times, and their relief at first had been so unsatisfactory and difficult, that my experience may be of value to others, for I have established a fact. I have already incidentally referred to this fact in a former communication, but not so clearly or with such certainty as I wish to do now.

When such cases come under my investigation, I immediately and invariably examine the urine, instead of the heart, and generally find it loaded with albumen. It is, therefore, highly important that the urine should be examined and the kidneys treated by nitroglycerine, rather than the heart auscultated and tonics prescribed, "because of the patient's extreme debility and feeble action of his heart, etc.," as is usually the case. I have sometimes found, on examination of the heart and pulse, that, besides the marked albuminuria, there exists a heaving heart and somewhat rigid arteries—conditions incidental, I believe, in adolescents, more to the "age of puberty" than to the state of the kidneys. But often, as in a case at present under my care, the heart is really feeble, and the pulse totally devoid of the signs of a kidney pulse; and had it not now been my invariable rule to examine the urine in preference to the heart, I should doubtless have prescribed a tonic regimen, to the detriment of my patient. The treatment for the two conditions is so opposite that I do not hesitate thus to call special attention to it: a feeble heart and pulse being relieved by tonics, good food, and stimulants; while congested kidneys are alone cured by a hot bath, nitroglycerine, an aperient, and milk only as a diet. With such treatment this syncope of adolescents is usually cured in a few hours, and with daily prudence for some time there will be no return of syncope or albumen, and the patient will express himself as vigorous again.

Cold as a Cause of Disease.—Hankel thus describes an interesting series of experiments, the results of which give some explanation of the intense visceral congestions which may be induced by exposure to cold of a relatively slight cutaneous area:

While prosecuting some investigations, in the years 1871–72, upon the temperature of the skin, I made an effort to study the influence which would be exerted upon the temperature of the skin by marked cooling off of one foot, and this with the view of clearing up the question of taking cold. For the purpose named, I put one foot into a basin of cold water. Immediately thereupon the temperature of the skin of the breast sank to a marked degree, so much so, indeed, that the needle of the thermo-electric pile I was using at the time ceased to record it. I was, therefore, not in position to determine the temperature of the skin of the breast, even approximately.

By evening I began to sneeze, and got so severe a cold that I was not willing to repeat the experiment a second time, and so did not mention it in my previous report.

It appears to me, as a result of this experience, that, by rapidly lowering the temperature of one foot, the temperature of the entire skin immediately sinks; and, as this can occur only as the blood is driven out of the vessels of the skin, it must follow that the blood is forced into the internal organs generally, or, what is more unfavorable still, into some particular ones, leading to an inflammation, or, as in my case, to a severe cold.

Whether this lowering of the temperature of the entire skin, by the cooling off of one foot, invariably results, or occurs when a cold is coming on, not having repeated the experiment, I cannot decide.—*The American Practitioner and News*, May 29, 1886.

Antiseptic Solution for the Hygiene of the Mouth and Teeth.—Dr. Müller, professor in the Dental Institute of Berlin, recommends for the purpose indicated, the following formulæ:

I.—Bichloride of mercury	. .	gr. iij.
Thymol	. . . . .	gtt. iij.
Distilled water	. . . .	O j.

Use as a mouth-wash for thirty seconds.

II.—Thymol	. . . . .	gtt. iv.
Benzoic acid	. . . .	gr. xlv.
Tincture of eucalyptus	. .	ʒ iij.
Distilled water	. . . .	O jss.

Use the same as that of formula I.—*Journal de Médecine de Paris*, May 9, 1886.

Treatment of Syphilitic Alopecia.—Mauriac commends, as a local application in alopecia of syphilitic origin, a pomade thus constituted:

Turpeth mineral,		
Quinine sulphate	. . .	āā 1 part.
Lard	. . . . .	60 parts.

In treating the rapid exfoliation of dandruff which often accompanies this disorder, he directs the application of the following lotion:

Borax	. . . . .	1 part.
Sodium carbonate	. . . .	2 parts.
Distilled water	. . . .	600 "

—*L'Union Médicale*, May 27, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 10, 1886.

CAUSES WHICH AFFECT THE PRODUCTION OF THE SEXES.

NOT long ago one of the most distinguished of French obstetricians remarked, referring to the pathology of puerperal eclampsia, "it is a bottle of ink." Most of those who have closely studied eclampsia will readily admit the truth of this statement. It may be added that like obscurity reigns over the subject of the production of the sexes, notwithstanding that the subject has engaged the attention of physicians and of philosophers from Hippocrates and Aristotle to the present time. Causes which were not causes have been alleged, and speculations which were mere artificial trees, having no life, and, of course, bearing no fruit, have abounded. A part of the work of modern science has been to destroy the errors of the past, and also to gather up the truths or the apparent truths it had collected.

How meagre our present knowledge upon the subject is may be judged by the fact that Stirling, in a note to his translation of the *Physiology* of Landois, quotes Hofacker and Sadler, whose investigations are half a century old, and on their authority asserts that if the husband is younger than the wife there are as many boys as girls; if the same age, the number of boys slightly predominates; but if he be older, then this predominance is greater. Nevertheless, BERTILLON, in his article upon "Natalité," in the *Dictionnaire Encyclopédique des Sciences Médicales*, has proved that these statements are not constantly true. Stirling also refers to the fact that in insects the food has a most important influence; but Pflüger, from his observation upon frogs, seems to conclude that it is without influence upon other forms of animal life, a conclusion which we believe is in the highest degree improbable.

The last number of the *Archiv für Gynäkologie* contains a contribution by CAMILLO FÜRST, upon the preponderance of male births from conception at the time of post-menstrual anæmia, or the period which immediately follows the menstrual flow. The article embraces many very interesting facts and probabilities, to some of which we will call attention. In the first part of this article, Fürst remarks that the two questions, when and how the final determination of the male and of the female sex is effected in man, animals, and plants, have hitherto been but unsatisfactorily answered by theories deduced from known facts. He further observes that the great interest manifested in this and other biological questions has found expression in the invention of theories and hypotheses which are frequently without any premises, or which, when really based on the result of investigations, lead to numberless contradictions, because, while investigating one factor, the influence of others has received little or no attention.

The first question, as it relates to man, is, Does this determination of sex occur before, during, or after impregnation? Certainly it must occur before we can distinguish the sexes anatomically. Statistics indicate that certain conditions before impregnation, as for example, the age of the procreator, his state as to nutrition and health acting upon the ovule, or upon the spermatozoid, result in the production of one sex rather than of the other. The question as to the influence of the time of impregnation in the determination of sex is one which can be more easily discussed than answered, and in our knowledge of this we have advanced little further than Aristotle. Further, various facts render it probable that certain conditions, such as nutrition, have an influence after impregnation in determining the sex. He thinks it also highly probable that the determination of sex occurs before, during, and after the impregnation of the ovum.

DÜSING, in his work "Die Regulirung der Geschlechtsverhältnisse bei der Vermachung der Menschen, Thiere, und Pflanzen," published in 1884, regards the greater preponderance of stillborn males over stillborn females as indicating the probable influence of nutrition in determining sex, for there is relatively a greater deficiency in nutritive material in the case of males than of females, since the former grow more rapidly, having an average greater weight. Another fact which favors this conclusion is that the embryos of almost all animals are at first hermaphroditic. The longer this hermaphroditic state remains, the greater the opportunity of changing the tendency toward the development of one or of the other sex. In the larvæ of the bee when the female genital system has begun to be developed, if there be insufficient food supplied, the development is arrested, and no queen bees are produced, but workers only,

and if the food be still further diminished those which would have been females become drones. Among higher animals, however, this early hermaphrodism seems a useless inheritance. The same principle is seen in the human race in the more frequent occurrence of hermaphrodism, in consequence of the late determination of sex, in multiple pregnancies; when more than one ovule is impregnated there is a competition between the two, a struggle for existence, and, hence, one is liable to suffer in development from deficiency of nutritive material.

Mayrhofer endeavored to refute this theory, which is an old one, by pointing to the fact that monstrosities are of the same sex; he believed that the sex was determined in the impregnation. Fürst answers him by saying that he forgets that a certain interval elapses between the time when the sex is determined after impregnation and the time when the first difference in the quantity of food appears. The chances for one or for the other sex, when this is determined after impregnation, may change in the same ovule before the final determination is made, and the last influence will have so much the greater power the less is that of previous influences.

In regard to the causes themselves, a variety must be assumed, and sex is the result of these combined influences. According to Mayrhofer, each parent has a tendency to produce his or her sex; this view Fürst regards as contradicted by statistical facts. In many forms of inferior animal existences, unimpregnated eggs always produce males. "If the wings of the queen bee are imperfect, so that copulation cannot occur while she is flying, or if she has used up her supply of semen, or her receptaculum be injured, or the spermatozoids are killed by frost, she lays unimpregnated eggs all of which are developed into drones." In view of all the knowledge we now have, the tendency of each sex is to produce the opposite sex. Fürst regards Düsing's law in reference to the regulation of sex in all animals as agreeing with this opinion. According to that law, all animals have inherited the peculiar power of being able to produce a preponderance of the sex which is deficient at a given time, that is, to supply a want. Now in delayed procreation in the human race—*e. g.*, in old primiparæ, or in multiparæ who give birth at long intervals, there is a preponderance of male births, and thus an actual deficiency of male births is made good. So, too, there is a preponderance of male births in primiparæ. There is a less preponderance of male births in unmarried women who become mothers, because impregnation usually occurs at an early age. After a war in which many males have been killed, there is a preponderance of male births.

Indirect causes are efficient in determining sex. Thus, when the constitution has become enfeebled, the sex of the individual will be produced. We can recall from our own observation some striking illustrations of the tendency of one sex to reproduce the opposite sex, and also of the truth of the statement that the enfeeblement of the individual causes the production of his own sex; one of each we will give. A., who was almost a Hercules in development, married a frail, delicate girl, who was scarcely half his size. Within six years she had three girls, but she became stronger and more robust, while her husband lost somewhat his physical vigor, and then a boy was born. B. married a healthy wife, he himself being in fair health; the first child, as is the more frequent in primiparæ, was a boy, and the next a girl; then the husband's health began to fail, and after a weary struggle for life during six years, he died of phthisis, his wife in the meanwhile having had three boys.

In addition to the nutrition, the vigor and the age of the individual are factors in determining the sex of the offspring. Each one at the time of greatest sexual vigor is least apt to continue his or her sex, and most apt to produce the opposite. In regard to the first of these propositions, Düsing's statistics are quite significant. He has recorded 861,640 births of colts: and found the average proportion of males to females 98.31 to 100. But if a stallion cover fifty or more mares the proportion of male colts to female varies from 100.7–101.19 to 100. If 20 to 54 mares were covered, it fell to 96, 60–97, 92 to 100. These statistics show that, obviously, the greater the vigor of the stallion the less probability of "getting" male colts, while that probability increased with the decrease of his vigor.

In reference to the second proposition, it would seem to sustain the Hofacker-Sadler law; but this law has in reality less influence than the absolute, not the relative, age of each. "As each declines from the standard of perfect sexual strength, the greater the liability of the production of his or her sex." Berner, studying the statistics of more than 200,000 births in Norway, has recently reached results which are in direct opposition to the Hofacker-Sadler law.

Fürst mentions an interesting fact in regard to animals in their native state, to wit, that they have the power of adapting the number produced to the environments; thus, when food is abundant there is a preponderance of female births, thereby promoting greater reproduction; but if food is scarce the number that can be reproduced is lessened by a greater number of male births.

In the human race statistics have shown that there is a lessened excess of male births in the wealthy classes and in cities, as compared with the greater preponderance in the working classes and in the

country, and that there is a transient increase in preponderance during a time of famine, depression, and war. Climate and seasons also have an influence. It has been observed that there is an increase in the number of male births before the extermination of a race.

All these considerations, with some others that are omitted from this analysis, lead Fürst to believe that there is an increase in the preponderance of male births when conception occurs in the early part of the period of post-menstrual anæmia. There is then deficient nutrition of the freshly impregnated ovule because of the uterine anæmia; and if defective nutrition can, at a later period of embryonic life, determine sex, how much more influential is such anæmia now! According to Düsing, the sexual development is influenced for three months by the nutrition of the mother. "It does not, therefore, seem that the chances for sex are very variable or equal, but rather that before any hermaphrodism can be demonstrated in the embryo, in some way in the dark recesses of germ-life the determination of sex has been made. Consequently, it is not a matter of indifference for the newly impregnated ovule, whether it reaches the uterus during the period of post-menstrual anæmia, or at a later period."

DRAINAGE OR PRESSURE.

THE importance of drainage in the dressing of surgical wounds is not only well recognized at the present time, but perhaps even exaggerated. Observation of the behavior of many operation wounds will show that drainage by tubes, or by means of strands of horsehair, brings to the surface so small a quantity of discharge that this step seems to be unnecessary. In the case of loss of substance by the removal of tumors, or by amputations, if it be possible to obliterate the resulting cavity or depression, drainage is quite unnecessary. This is plausible in theory, and it is found to be true in experience. It is now a good many years since Gamgee began strenuously to advocate the principles of dry and infrequent dressings, and those who have adopted these principles can bear witness to the fact that they have not been disappointed in the results. It is also probable that no small share in the success of dressings with various powders, such as iodoform, naphthalin, and bismuth, is to be attributed to their physical properties.

MAYDL recently reported in the *Centralblatt für Chirurgie*, for April 10, 1886, the results of close suture without drainage, in the clinic of Prof. Albert. Within a year the latter treated, among others, thirty-two amputation wounds in this way, and lost but one patient, who died of secondary hemorrhage. In several of his cases of amputation of the leg it appears that Albert pushed the idea of compression a little too far; for gangrene ensued in three out of eleven cases. In operations upon tendons, bones, and joints, his experience indicates unmistakably the utility of drainage.

It appears from a review of what has been accomplished without drainage, that the success of this method depends upon the possibility of approximating all fresh surfaces and maintaining them in apposition, without the use of so much pressure as shall seriously interfere with the circulation of the part. Where this can be done drainage is not called for. But, as there is always uncertainty on this point, and as it does not appear that any reasonable method of securing drainage has material disadvantages, it is not wise to discard it for close suturing which, when it succeeds, offers but little better results.

CHILDREN'S AID SOCIETIES.

THERE is no object more deserving of sympathy and kindly aid than that which affords to the helpless little ones of our crowded cities an opportunity of enjoying, for a brief period, the benefits of a sojourn in the country. A change of air and surroundings, even though for a day, is of the greatest advantage to the health, and certainly contributes to the enjoyment of children, who, through stress of poverty, are denied fresh air, wholesome food, and the ordinary comforts of life. Under such circumstances, the hot season is especially trying to the weak and sickly, and unless promptly rescued they speedily succumb to the unfavorable influences by which they are surrounded. This broad field for benevolent work has not been neglected. The Children's Country Week, the Sanitarium in Philadelphia and in Baltimore, the St. John's Guild in New York, and kindred societies in other cities, are accomplishing wonderful results, but their labors are necessarily restricted by limited resources.

As auxiliaries to the local sanitary authority in the employment of measures for the preservation and improvement of the public health these aid societies are of undoubted utility. But the city government cannot contribute to their support, though such assistance would promote public economy. These organizations must be wholly sustained by the generous offerings of the public, and to it the appeal is once more made.

The physician has unusual advantages for directing attention to these noble enterprises. No one knows better than he does the needs of the children of our poor at this season of the year, and his opportunities for enlisting the sympathy and generous aid of our wealthy citizens should not be suffered to slip away unimproved.

THE MEDICAL DEPARTMENT OF SHAW UNIVERSITY.

SOME two years ago, soon after the Medical Department of Shaw University had been founded, we

commented in these columns on the fact that it was the first medical school in this country that had made a four years' course compulsory, and commended the school on the wisdom of its action.

We are glad to learn that the result has justified what we then asserted, and moreover has shown the entire fairness of the State Medical Board of North Carolina. This spring the first class of six young colored men graduated in medicine at Shaw University, and three of them decided to practise in their native State. After an examination by the Board all three of them were admitted to practice, while of the white candidates we regret to say that one-fourth failed to pass—a sorry commentary on their knowledge.

REVIEWS.

Insomnia, and other Disorders of Sleep. By Henry M. Lyman, A.M., M.D., Professor of Physiology and of Diseases of the Nervous System, in Rush Medical College; Professor of Theory and Practice of Medicine in the Woman's Medical College; and Physician to the Presbyterian Hospital, Chicago, Ill. Pp. 239. W. T. Keener: Chicago, 1885.

The author of this interesting little book is evidently no mere routine practitioner, but a gentleman of culture who has read and thought much respecting the mysterious "brother of death," which Sir Thomas Browne declares takes away the third part of our lives. After considering the nature and causes of sleep, in regard to the latter of which Dr. Lyman accepts the theory of Pflüger, a chapter is devoted to the various influences which produce insomnia, arranged for study in two groups,—viz., first, those inducing wakefulness by irritation of peripheral portions of the sensory apparatus; and, second, those morbid states of the central nervous organs which disturb the normal recurrence of sleep. In the section on remedies for insomnia, little that is novel is presented except the remarks upon paraldehyde, which, in spite of its disagreeable taste and smell, is recommended as preferable to chloral hydrate in cases where there is no disease of the stomach, where the wakefulness is not dependent upon pain, and where it is associated with cerebral hyperæmia. An important advantage claimed for this hypnotic, is the absence of a period of excitement, such as follows the administration of chloral and immediately precedes the advent of refreshing slumber. The latter half of the volume is chiefly occupied with the subjects of dreams, somnambulism, and hypnotism, rendering it of more interest to the student of physiology than to the medical practitioner.

SOCIETY PROCEEDINGS.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, June 14, 1886.

Dr. C. D. Palmer read a paper on

THE EARLY DIAGNOSIS OF CANCER OF THE CERVIX UTERI.

It is stated on good authority, he said, that cancer is three times more frequent in women than in men, and that one-third to one-half of the total number of cases in women involve the uterus. It is a disease three times more frequent in the uterus than in any other organ of the body.

A comparison of the past and the present favors the opinion that cancer is occurring with increasing frequency. Without doubt this increase is largely apparent, the result very naturally of improved methods of diagnosis and more frequent examinations of the female pelvic organs. But there is reason to believe that the increase is not seeming only, but real; a result of the growing changes in the habits of living among modern people, for cancer is a disease which statistics tend to show follows in the wake of civilization. Its frequency and fatality among women seem frightful when it is estimated that three per cent. or more of their total mortality from all causes is by its ravages, and that it explains more deaths than any other pelvic disease peculiar to the sex.

The strong conviction, based upon clinical experience—a conviction growing stronger—that cancer is primarily a local disease, and that the system is implicated secondarily, has impelled surgeons to extirpate the diseased tissue as thoroughly as possible, consistent with life and the integrity of the surrounding parts. It has founded the practice that to be successful extirpation must be early. A very large proportion of the cases of uterine cancer are necessarily fatal, sooner or later, when first seen—fatal because the surrounding parts are so involved that entire extirpation is impracticable and impossible; fatal because the day of grace has been sinned away. If this fact is not clearly appreciated before any operative procedure, it becomes plain during it.

While these facts, which few, perhaps, will contradict, have no direct bearing on the subject of this paper, nevertheless they possess that degree of vital importance which ought to stimulate everyone concerned in gynecological practice in efforts to recognize as early as possible the true character of uterine cancer and its semblances.

The diseases of a malignant type which affect the uterus are carcinoma, epithelioma, and sarcoma. The first two, at least primarily, almost always involve the cervix uteri; the last, with the same uniformity, the body of the uterus. Schröder says that less than two per cent. of uterine cancers affect the body of the organ first. Most authors make a still greater difference. County says 1 in 429 cases. The corroding ulcer described by the Drs. Clarke, of London, affecting the cervix, is exceedingly rare, and is undoubtedly a form of epithelial cancer. Epithelial cancer, then, may be of the vegetating or ulcerative variety. The clinical differences between any of the above varieties of cancer, including cancroid (so-called), may, at the beginning, be easy of recognition, but as the disease advances, the superficial parts being more or less destroyed and the deep structures involved, a differentiation is not only difficult but may be impossible.

The benign affections of the cervix which at some time may be confounded with the malignant, are chronic inflammation, so called; a diffuse interstitial cervical metritis; a condition commencing with hyperæmia merging into hyperplasia, leaving the structures enlarged, irregular, and indurated. Associated

with these conditions, very often independent of them, we find endometrial inflammation with its results, erosions, granular and cystic degenerations, ectropion, the surfaces being the seat of various discharges of mucus, pus, or blood. It is true that syphilitic ulcerations and condylomatous formations, also fibroid infiltrations and tumors, may be mistaken for malignant disease, but their existence is not only less frequent than the aforementioned benign affections, but an error of this kind is certainly less likely to be committed.

Nothing can be easier than the diagnosis of most of the benign diseases of the cervix uteri. Nothing can be plainer than the determination of the presence of advanced cancer of this part of the uterus, by far the most common site. So characteristic is the ulceration, so deep the destruction and excavation of the tissues, so involved by its peculiar infiltration are the surrounding parts, so pronounced the symptoms, both general and local, that touch alone is ordinarily all sufficient. A combination of symptoms and local signs are present which no other disease fully simulates. By this time anything in the way of treatment is only palliative, and hence, while a correct diagnosis is important enough, practically life does not hang upon the decision. As it is of vital importance that we recognize a malignant disease of any type early, if we would do any radical or permanent good, and as mistakes are most generally made in the earlier stages of the disease, let us more fully consider this subject. Excluding from present consideration cancers of the uterine body, which are rare, for practical purposes we may divide the subject into two parts.

I. The form of cancer simulating or confounded with parenchymatous or fibrous benign diseases of the cervix.

II. The form of cancer mistaken for, simulating, or simulated by, endometrial diseases.

Exactly what anatomical structure which, in point of origin, undergoes the primary change in cancer is uncertain. Ruge and Vect say that the disease may originate in the connective tissue, in papillæ, glandular epithelium, and superficial epithelium. Probably the origin of carcinoma begins in a degeneration of the connective tissue cells, either under the mucous membrane of the vaginal face of the cervix or up within the cervical canal, while the epithelial growths or ulcerations first invade the superficial epithelium.

I. A carcinomatous infiltration arising within the connective tissue cells of the cervix, at once heightens the vascularity of the part, which in color looks reddish or bluish, produces nodulations more or less hard, and reduces the mobility of the superjacent mucous membrane—conditions which, when seen before characteristic ulceration has commenced, are nearly identical with changes brought about by a local hyperæmia, followed by a hyperplastic infiltration of the connective tissue. Should these changes of a commencing malignancy start in a cervix previously healthy, or so little diseased as to excite no special attention, they progress so insidiously—it may be slowly—that in all probability the patient will not call upon her physician until the second or ulcerative stage has advanced. Or should they commence in a cervix already diseased by chronic inflammation, one that is being inspected for treatment from time to time, they may even advance to a considerable degree before any special suspicion is excited.

The general health, either with a local condition of malignancy or innocence, may be good or bad (in incipient cancer not engrafted upon any local inflammatory state, it is frequently very good), while the local symptoms, pain, leucorrhœa, and menstrual aberration, are not unlike. Can a diagnosis now be made of the disease in its exact nature? In most instances, I think it can. The one thing needful is that a suspicion of malignancy be aroused; and if attention be directed to certain symptoms and signs, this suspicion as a rule may be dismissed or confirmed. In incipient malignancy, the redness arising from local congestion is more intense; if the epithelium is lost, the papillæ below are more prominent, and these bleed more easily upon touch; the circumscribed induration is more marked. The whole cervix may not be especially enlarged, is not tender to touch, and the whole uterus is mobile. The diagnostic test suggested by Spiegelberg, in 1871, (*a*) that the mucous membrane in a cancerous growth is firmly connected with the underlying induration and immovable over it, and not so in hyperplastic thickening and induration; and (*b*) that the hyperplastic induration under the pressure of compressed sponge in the cervical canal becomes regularly looser, softer, and thinner, the cancerous induration remains unaltered, hard, rigid, and cannot be stretched, is not as reliable as was at first supposed, even if practicable. But much valuable information can be gathered by carefully watching the developments of treatment; hence, it may be necessary to keep a patient under observation for a short time for diagnosis. It will be observed that, while all the local conditions, leucorrhœa, erosion, induration, etc., do improve under a well-directed local treatment, provided they are the offsprings of an inflammation, at the same time they do not at all, or but slightly—never permanently—change for the better, if malignant; but they manifest a special obstinacy to treatment—in fact, they progressively get worse. The leucorrhœa increases, the papillæ enlarge, and the erosion extends, the induration deepens, and the congestion becomes more intense. I think this is especially marked if the local treatment is of a caustic or irritating character.

Such developments should excite the gravest suspicions, notably in women of advanced years. If any doubts now remain, a small section of the indurated tissue should be excised and thoroughly examined under the microscope. Although there is no distinct cancer cell, a large aggregation of epithelial cells, with nuclei arranged within a fibrous stroma with alveolar spaces, is thought to be typical. I have great doubts whether microscopists by their examinations can, always, or in most cases, give us reliable opinions, without any other clinical evidences at hand; but with them, the microscope becomes strongly corroborative and confirmatory.

Whether chronic metritis proper—chronic interstitial metritis—has a tendency to be transformed into malignant disease, has been a matter of much disputation. Noeggerath, who ably considered this subject several years since, took the affirmative side of the question.

II. Under the second heading, the form of cancer which is confounded with endometrial or mucous benign diseases, is epithelioma.

In either class of diseases under consideration—paren-

chymatous or mucous—an error in diagnosis may be made in either direction, of course; the benign taken for cancerous, or *vice versa*. Early carcinoma of the cervix proper is, I think, often overlooked, the disease being interpreted more frequently as inflammatory, than otherwise. But not so with an endometrial growth: the disease now much more frequently being supposed to be malignant where it is innocent. In reference to this point, I can recall numerous instances in my own practice and that of others, where the diagnosis of malignancy has been made for the time being, and it is easy to understand how certain cases may be reported as having been cured by an operation of cervical amputation or excision, when no cancer whatever has been present.

The first, the great cause in the formation of epithelial growths of the cervix uteri, is laceration occurring during parturition. If this has not healed primarily, especially if bilateral, it leaves the cervical walls gaping, and, sooner or later, a progressive hyperplasia, papillary and follicular, increases the size of the cervix, creates erosion of the separated lips, which become covered with a mass of fungoid granulations. These fungoid granulations, an outcropping of a perverted nutrition, spring up in nature's efforts to repair a local injury. They may develop within a comparatively short period after the laceration, or many years later, even after the climacteric period. They are at first, and may always, probably, continue to remain innocent formations—benign papillomata or epitheliomata, so to speak, if not excessive.

On the other hand, however, with an uncertain degree of frequency, they may quickly develop into malignancy. More often this change comes later on, merging insensibly into degeneracy. The frequency and rapidity of this degeneration are determined, there is reason to believe, by certain constitutional states, not in themselves cancerous, but such as afford a fertile soil for this kind of growth. The fact that the transformation may be exceedingly slow, consuming years, is an important one. It proves that, because the laceration with its results has lasted a long time, we ought not to be thrown off our guard as to the supervention of what is much more than a mere possibility. For some time before, during, and even after the transformation, the local appearances may not be greatly unlike, hence the liability to an error in diagnosis. The whole uterus has almost its natural mobility, there is no noticeable parametritic infiltration, the body of the organ is not implicated; the entire disease is limited to the cervix, and this part presents the physical conditions, mushroom-like in shape, covered with masses of vegetating fungosities, or there is a well-defined excavation, a true ulcerative action.

The relation of erosion, eversion, and granular degeneration, arising from lacerations of the cervix, to the development of epithelioma, as cause and effect, was first pointed out by Briesbey, and has been repeatedly referred to by Ruge, Veit, Emmet, and others. The last-named authority says that he believes that nearly all, if not all, cases of epithelioma of the cervix have their exciting cause in a laceration. The fact that epithelial cancer is exceedingly rare in virgins, or in women who have never been pregnant; that the disease exists most frequently in women who have had children in number above the average; and that in almost every case, unless the disease is so far advanced as to have produced much destruction of tissue, the old line of laceration and cicatrization can be marked out by the finger, proves that the belief of this distinguished authority is so well founded as to end all controversy in this direction.

Unquestionably malignant, epitheliomatous degeneration is more likely to ensue in cases of cervical laceration in which the torn surfaces never cicatrize. But cicatrization, whether by nature or art, is not, by any means, a complete barrier. Cicatrization does not do away with the ill consequences of laceration, eversion, hyperplasia, and follicular degeneration; and from the deep layers of the squamous epithelium of the everted surfaces, or from the greatly increased glandular epithelium, a cancerous growth may spring up. Siredey and Daulos (quoted by Parvin) say that benign papillomata are more friable, bleed more easily, and are implanted upon a broader base than the malignant. But not only are these differences not pronounced, but they cannot be depended upon in diagnosis.

It is very probable that the microscope will not afford evidence for a positive conclusion until the disease is well advanced, but its use should always be brought into requisition.

Topical treatment, in the absence of the microscope, or before its employment, can always be found to be a very valuable guide for diagnostic purposes. The local application of such an emollient as boroglyceride, of such astringents as the glycerite of tannin, or alum, once in two or three days; the shaving off of fungoid granulations with the scissors, or their removal with a sharp curette, followed by the above medicaments, will almost invariably so wonderfully improve the condition of the parts, in from a few days to a few weeks, provided the disease is inflammatory and benign, as to put at rest all suspicions of malignancy. On the other hand, such treatment, it matters not how skilfully directed, can only be slightly, never progressively, beneficial, when the cancerous degeneration is fixed. In quite a number of cases, both in public and private practice, where large masses of benign granulations have sprouted up over deeply lacerated and everted cervices, presenting the physical aspect of malignant epithelioma, when the general health, in consequence of a profuse leucorrhœa and menorrhagia, was being undermined, and when doubts arose as to the real nature of the local difficulty, the treatment referred to has quickly settled the diagnosis by the results obtained.

We all know that epithelioma of the cervix uteri of the vegetating kind is the least malignant of all malignant growths; purely of local origin, localized for an indefinite period, possibly for years, disseminating itself through surrounding structures very slowly. Removed reasonably early, permanent relief is not only possible, but probable. And not only ought extirpation to be early and thorough in epithelioma, but the cause giving rise to, and conditions simulating and degenerating into the same, should receive proper surgical attention. Whilst the outlook is less favorable for a carcinoma proper, the same principles hold good. Suspicious cases should be subjected to the most rigid scrutiny, all diagnostic tests being applied. Doubts may still remain. But truly doubtful cases should come under the same class demanding operative treatment. If now and then

one is subjected to treatment not absolutely needed, a greater number will obtain a measure of relief, a prolongation of life, and an easier death.

ONTARIO MEDICAL ASSOCIATION.

Sixth Annual Meeting, held at Toronto, June 2 and 3, 1886.

(Specially reported for THE MEDICAL NEWS.)

THURSDAY, JUNE 3.—SECOND DAY.

DR. HENDERSON, of Kingston, read a paper on a

GLIOSARCOMA INVOLVING THE PITUITARY BODY,

and presented the specimen from a man under his care in the hospital at Kingston.

DR. F. R. ECCLES, of London, introduced

THE DISCUSSION ON PUERPERAL ALBUMINURIA.

He first dealt with the minute anatomy of the kidney, composition of the urine, and the method of its elimination, and pointed out that the present state of science does not enable us to explain the absence of albumin from the urine in health. He next referred to the physiological changes in the uterus, pelvic lymphatics, portal system, spleen, liver, etc., during gestation. These changes give rise to great increase in the effete matter in the blood; hence the greatly increased activity of the emunctories, especially the kidneys. The increased waste results in increased tension of the vascular system. He believed it is in this direction we would have to look for the cause of albuminuria.

By many the pressure of the uterine tumor has been assigned as a cause; but this explanation is insufficient, as ovarian and other tumors rarely cause albuminuria. The effect of gestation was next dealt with. The presence of albumen in the urine may continue without any disturbance; abortion may result and save the patient from worse consequences; it may result in eclampsia. The existence of renal disease before pregnancy renders the prognosis especially grave. The treatment was briefly reviewed. The disappearance of albuminuria after the death of the fœtus in utero and after delivery indicates the course to be pursued in severe cases. Whether to try to conduct the case to full term, taking the risk, or to terminate the gestation and avoid the risk, is often difficult to decide; it is, however, better to lose twelve children than one mother.

DR. A. H. WRIGHT, of Toronto, said it was well to sum up all the physiological changes in pregnancy, but they are physiological after all. To put them and albuminuria as cause and effect is manifestly improper. In the management of these cases we have to remember two things, viz., the blood is impoverished and poisoned. Therefore, tonics, of which tr. fer. chlorid. is best, are required to improve the anæmia, and all the emunctories are to be stimulated to remove the deleterious matters from the blood. He had very serious objections to operative treatment—it produces too much shock, and is not to be resorted to until all other means have failed; if the case cannot be allowed to continue longer, labor is to be induced.

DR. ROSEBRUGH, of Hamilton, said it was of the utmost importance to ascertain whether kidneys were healthy before pregnancy, as few cases in which Bright's disease occurred could be allowed to go on to full term. He dissented strongly from the doctrine that pregnancy should be terminated as soon as the presence of albumen in the urine is ascertained. The case should be guided and watched, but pregnancy is to be terminated only for the gravest cause.

DR. TEMPLE, of Toronto, agreed in the main with the opinions advanced in the paper. He had long since abandoned the theory that pressure of the uterine tumor caused the albuminuria. The cause may perhaps be found in the increased arterial tension as indicated by the late Dr. Mahomed. He relies chiefly on morphine in convulsions, giving it in half grain doses hypodermatically, every two hours or more as needed.

DR. MOORE, of Rochester, said that the old authors described a condition of albuminuria chronic in character, requiring persistent catharsis. He cited some cases, agreeing with such a description, coming under his own observation. In these he selected Epsom salts as best meeting the requirements, being efficient and but little irritating. Enough should be given to produce three motions daily. He had continued such treatment for many months in cases of albuminuria with very severe dropsy. At first the improvement was slow, but it was ultimately quite satisfactory. One such case was seen twenty years after in perfect health. He became convinced that one of the most powerful agents, even in organic disease, is steady laxation. There are conditions of chronic albuminuria of non-organic kind which, if not interfered with, will become organic, terminating fatally, but which may be interfered with and cured.

He knew no better agent in the albuminuria of pregnancy than Epsom salts given as above. It is entirely free from danger of producing miscarriage. If albumen does not diminish, it keeps the patient free from bad symptoms as headache, nausea, etc., and she is carried along safely. In puerperal convulsions he would give a large dose of calomel—it is slow but sure. Follow it in a short time by a *terrific rider* of croton oil. In mean time to suspend convulsions, give ether—it will stop them for hours but not permanently arrest them. It should be given sufficiently freely to keep the patient fully under its influence. It may be given with perfect safety when the patient is in deepest coma; it is a mistake not to give it then, and so prevent further convulsive attacks. As soon as the calomel and croton oil act he feels that his patient is quite safe and she can be left without any further concern.

Drs. MacDonald, of Hamilton; Brouse, of Brockville; Ferguson, of Toronto; Mitchell, of Enniskillen; and Harrison, of Selkirk, also took part in the discussion.

DR. MCKINNON, of Guelph, then reported *Some Cases of Ovariotomy.*

AFTERNOON SESSION.

DR. DUPIUS, of Kingston, read notes on a case of *Multiple Hepatic Abscesses with Petrifaction of Gall-Bladder.* The petrified gall-bladder was about two and a half inches long and resembled in size and shape a partly flexed middle finger.

He also read notes and presented a specimen of *Malformation of Rectum and Anus (Congenital)* in which the rectum opened into the bladder.

OFFICERS FOR THE ENSUING YEAR.

The Nominating Committee presented their report as follows, which was adopted:

President.— Dr. J. H. Richardson, of Toronto.

Vice-Presidents.—Drs. Harrison, of Selkirk; Brouse, of Brockville; Moorhouse, of London; Aylesworth, of Collingwood.

Corresponding Secretaries.—Drs. Fraser, of Sarnia; Harris, of Brantford; Aikin, of Collingwood; and Gibson, of Belleville.

General Secretary.—Dr. J. E. White, of Toronto.

Treasurer.—Dr. N. A. Powell, of Toronto.

Time and place of next meeting—Toronto, on 1st Wednesday in June, 1887.

DR. MCFARLANE, of Toronto, gave a short address on

THE SURGICAL TREATMENT OF DIPHTHERITIC CROUP.

The methods of treatment must vary with the type of case. Some die from heart failure, some from œdema of lungs, some from the poison of the disease, etc. The point on which he wished to elicit discussion was as to the propriety of performing tracheotomy in this disease. He believed diphtheritic and membranous croup two distinct diseases. In the latter, tracheotomy should be done when necessary to relieve the laryngeal stenosis; in the former, the propriety of operating is doubtful. He had operated in twelve cases; three were membranous croup, and two recovered; nine were diphtheritic, and all died. In the statistics of cases operated on no distinction was made between the two diseases. In diphtheria, exudation is likely to occur on any point that is irritated, hence it would probably form on the trachea at the point irritated by the lower end of the tracheotomy tube and spread downward.

DR. G. R. MCDONAGH, of Toronto, then presented a paper on

THE IDENTITY OF CROUP AND DIPHTHERIA,

in which he considered first the supposed anatomical pathological differences, and, secondly, the alleged clinical differences in the two diseases. After referring to the theory of Virchow (which he himself afterward abandoned as inadmissible) that the exudation in diphtheria was formed *within*, and that in croup *upon* the mucous membrane, Virchow's later theory of the tissue necrosis beneath the false membrane was discussed. Several eminent authorities were quoted to prove that this feature is not a real distinction, but only a difference in degree, and also that tissue necrosis exists in croup as well as in diphtheria. The difference in the degree of adhesion of the exudation to the mucous membrane was explained by the physiological and anatomical differences of the pharynx and larynx, and particularly with regard to the epithelial layer, which, in the larynx, is separated from the underlying tissues by a distinct homogeneous basement membrane, whilst that in the pharynx passes gradually into the tissues beneath without separation. On microscopical examination it is admitted by pathologists that no real distinction can be detected. The descriptions of Dr. E. Wagner, probably the best authority, show no practical difference.

The clinical aspect was then discussed. Difference of site could not be considered as a real distinction, for not only do we find cases of diphtheria extending to the larynx, and cases clinically answering to croup extending to the pharynx, but we have the best authority (Sir William Jenner) for saying that true diphtheria may be limited entirely to the larynx. The reason that this is not more frequently seen to be the case is often due to want of the requisite careful examination by the physician. With regard to the alleged non-contagiousness of croup, it was argued first that not unfrequently so-called croup does spread, as, for instance, when one member of a family is attacked with the regular form of croup and afterward other members of the same family contract diphtheria. Secondly, when the disease does not spread the original case may have been only one of simple acute laryngitis with dried catarrhal secretion, and not one of membranous croup at all. Thirdly, that the fact of the disease not always spreading is no reason that it is not diphtheria. The different degree of the general toxæmic effect and the swelling of the neighboring glands was explained most fully on physiological and anatomical ground. The writer held the opinion that the toxæmia is due in part, at least, to absorption of septic matter from the diseased parts. After showing the great richness of the lymphatic absorbent supply in the pharynx, and the connection with the glands about the angle of the jaw, and in contrast the very scanty development of the lymphatics and paucity of glands in connection with the larynx, the writer argued that here is to be found the chief cause of the severe adynamia in diphtheria, and, further, that the same cause is responsible for the greater frequency of albuminuria in diphtheria, and perhaps also for the paralysis. The case of Hüter's of undoubted croup was quoted, in which complete paralysis of the pharyngeal muscles took place. The writer believed, for these reasons, that so-called membranous croup and diphtheria are the same disease with different sites of local manifestation.

DR. CRONYN, of Buffalo, had no doubt that diphtheria is a constitutional disease and that true croup is always true diphtheria, and, therefore, always also a constitutional affection. Twenty-three years ago his finger was bitten by a child suffering from membranous croup. Eight days later a little pellicle formed at the seat of wound; after four days he had malaise, headache, and in three days more his throat was sore and he was very ill. He passed through a severe attack of diphtheria. From his own experience he entirely objected to local treatment on account of the suffering it produces as well as on account of its inefficiency, owing to the disease being constitutional. He would in no case perform tracheotomy.

DR. W. T. AIKINS, of Toronto, had opened the trachea in many cases. They all died. If they recover after tracheotomy, their recovery is not due to the operation.

DR. PALMER, of Toronto, said there was a line of successful cases of tracheotomy in true diphtheritic croup down to the present from the time of Trousseau, who had one successful case in four. They are sure to die without the operation; we should, therefore, give them the benefit of any chance afforded by it.

DR. MCPHEDRAN, of Toronto, said that tracheotomy has saved many cases of diphtheritic laryngitis is established on the most indisputable authority; it is too late, therefore, to challenge it as a proper operation in many cases. He believed that not a few cases are lost

through inefficient nursing after operation; it is useless to operate unless the child receives the most skilful management. In many cases of catarrhal inflammation of larynx and trachea the secretion becomes so inspissated as to appear almost membranous; this is strongly emphasized by Professor James. These cases present symptoms indistinguishable from those of membranous croup. Such a case came under his own observation lately in a child, one and a half years old, who was recovering from scarlatina. After the symptoms of croup had disappeared, death took place from a low form of pneumonia. Doubtless many cases of recovery after tracheotomy were just such as this one. He desired to enter his protest against the directions for treatment of diphtheria given by almost all the authorities. They give specific directions for frequent local applications to be made to children without any cognizance being taken of the impossibility of doing so in the majority of cases without a struggle, in which the child suffers more injury than can be counterbalanced by the entire local treatment.

Dr. Atherton, of Toronto, said that he had had a case recover after tracheotomy in which membrane formed on the wound and the father had diphtheritic membrane form in the pharynx. He thought acute croupal cases unsuitable for operation; the more gradually the stenosis is developed, the greater the prospect of recovery. The same rule holds true in diphtheria, in which the deposit occurs on any part.

Dr. Palmer, of Toronto, followed with a paper on *Diseases of the Eye in Pregnant Women*.

Dr. A. H. Wright, of Toronto, read a paper on

SECONDARY PUERPERAL HEMORRHAGE,

the conclusions of which were that nearly all cases are due to retention of pieces of placenta and that the proper treatment is to explore the uterus.

A LARGE URIC ACID CALCULUS.

Dr. Aylwin, of Kingston, showed the cast of a calculus, oval-shaped, measuring nearly twelve inches in longest diameter, and weighing about twenty ounces. It was removed by the suprapubic operation. It was the largest uric acid calculus on record.

Dr. Tremaine, of Buffalo, said the suprapubic method was by far the safest cutting operation. By it you avoid the possibility of hemorrhage, also injury to the genital apparatus. He believed the latter consideration of great importance, especially in children. Of seventeen cases of children cut by the perineal section reported by Dr. Halberstadt, of Pottsville, Pa., only one had issue. It was best to suture the bladder in ordinary cases, but in cases in which there was cystitis, etc., an opening had better be left for drainage. The existance of an enlarged prostate was an additional reason for preferring the suprapubic operation to perineal section. The bladder was more easily entered, and if a small central elevation existed at the neck of the bladder, it could be pinched off. The peritoneum is in some danger of being wounded, but with care can be avoided. It was opened in one of his own cases, and bowel protruded. A suture was passed through the abdominal wall and bladder, and the man recovered without a bad symptom. In no case had hernia followed the operation, so far as he knew. He believed the operation would give better results than even rapid lithotrity.

Dr. W. T. Aikins, of Toronto, referred to some cases in his own experience, in one of which there followed hernia.

Dr. Cameron, of Toronto, was strongly in favor of the high operation, especially in children, on account of non-interference with the genitals, and of the high position of the bladder. He, however, took issue with Dr. Tremaine in cases of enlarged prostate, because in these the prostatic trouble is capable of greater relief by perineal section. Besides, in these the stone cannot be raised out of the pelvis. He drew attention to the fact first pointed out by a London surgeon, that the bladder, when forced up, has its posterior surface brought upward and forward, and exposed to the line of incision.

Evening Session.

Dr. Oldright, of Toronto, presented a paper on

SOME POINTS IN THE TREATMENT OF COLLES'S FRACTURE.

He said that great pains should be taken to secure perfect coaptation. The splint used is usually too long; it should extend only as far as the first phalanges at first, so as to allow of passive motion at end of eight or ten days. This is of special importance. The splint should then be gradually shortened, till it extends only to the metacarpal bones. Bandages should not be applied very tightly.

Dr. Moore, of Rochester, said there was great inequality in the results of treatment of this fracture; one was good, and another bad. He then discussed the anatomy of the wrist, pointing out that the hand is wholly supported by the radius, the ulna being separated by the intervention of the triangular fibro-cartilage which is attached by its apex at the base of the styloid process. The force causing the fracture might be of three degrees; 1st, just sufficient to break the radius; less than this would simply sprain the wrist; 2d, the balance of force after fracture causes dislocation of ulna, in which the triangular cartilage is torn from its attachment at the base of the styloid process, or, more frequently, the styloid is broken off, leaving a pointed base, which is forced into the anterior annular ligament, from which it is often with difficulty dislodged; 3d, the force is so great as to lead to a compound luxation, the ulna being driven through the skin beside the pisiform bone. He had reached these conclusions from the results of a number of post-mortem examinations of recent and old fractures.

In the treatment of simple cases without dislocation, any kind of splint, pistol or other, usually gave good results; but if there was dislocation of the ulna, the pistol splint made matters worse, and unless the luxation is reduced, no kind of treatment gives good results. He then explained the method of treatment devised by himself, and demonstrated its application on the arm of one of the audience. In cases that came to him with bad results he had not hesitated to break the bone again as long as six months after the accident, but after that the union is too firm to render this method advisable. In such cases the end of the ulna may be removed with much benefit. He removes the dressing, in all cases, in three weeks, and resorts to passive motion very early in the treatment.

Dr. Cameron, of Toronto, related some cases under his care, in which there was dislocation. They were

treated after Dr. Moore's method, with the most satisfactory results. He pointed out that dislocation might be prevented by impaction of the fracture. He concluded by moving a vote of thanks to Dr. Moore for his exposition of his views on this fracture and his method of treatment.

Dr. Jones, of Port Perry, in seconding the motion, said he had followed Dr. Moore's teaching for the last sixteen years, and his results had been almost invariably satisfactory. The motion was most cordially assented to.

The President-elect was then conducted to the chair and took his seat amid applause. He briefly returned thanks for the honor conferred on him.

After the usual complimentary motions, the Association adjourned.

CORRESPONDENCE.

THE MEDICAL SCHOOL OF MAINE.

To-day the Medical School of Maine held its sixty-sixth graduation exercises, and added twenty graduates as its contribution to the ranks of the profession. Until the organization of the Bowdoin Medical Alumni Association, in 1884, these exercises were confined mainly to reading two or three theses, and the public presentation of diplomas by the President of Bowdoin College. Now they are held in the Memorial Hall of the College, increased by a formal address by some invited guest and a valedictory from a member of the class, and rendered more attractive by choice music and daintily engraved programmes, and crowned by a general reunion and banquet given by the Medical Alumni. All of which argues well for the progress and zeal of the Alumni and the good taste of graduating classes.

The exercises of to-day were characterized by a most excellent address from Rev. Wm. H. Fenn, D.D., of Portland, who selected as his subject "The Moral Element in the Physician."

The valedictory address was then made by Wm. Lawrence Dana, A. B. (Harv.), of Portland.

After the presentation of diplomas, the annual meeting of the Medical Alumni was held, and the following officers elected.

President.—H. H. Hunt, M.D., of Portland.

Vice-Presidents.—D. A. Robinson, M.D., of Bangor, B. F. Dunn, M.D., of Windham.

Treasurer.—F. H. Gerrish, M.D., of Portland.

Secretary.—C. D. Smith, M.D., of Portland.

Following adjournment, the Alumni and their guests repaired to the dining-room and sat down to an elegant banquet.

The chief interest of this portion of the entertainment centred upon the remarks of President Hyde, in response to the toast "Bowdoin College," which gave an inkling of the sentiment of the Trustees relative to the change of the school from Brunswick to Portland. With the members of the Alumni Association this change has become a fixed purpose; the great body of the Alumni desire it, the Faculty of the School are anxious for it, the Maine Medical Association has asked it, and the best interests of the School urgently demand increased facilities for clinical study.

As one of the professors, himself a graduate of Bowdoin College, has said, the School has always been an *honor* to the College, and *never* an expense; the College is asked to put itself to no expense now, yet the plan has been hampered, thwarted, and delayed, and with no reasonable explanation. A committee of conference, respectfully appointed by the Maine Medical Association, was regarded with the utmost indifference, and the medical fraternity begins to feel that such ultra-conservatism ought to have some limit.

The President's remarks indicated the same reluctance on the part of the Board as heretofore, and he very happily likened the school to the blushing maiden whose parents are reluctant and fearful to let her go unhindered to the arms of her first suitor.

The worthy Professor of Medical Jurisprudence, in replying to the sentiment, "The Faculty of the Medical School," detracted somewhat from the force of the eloquence of the President, by remarking that it ought to be reasonably certain that a blushing damsel of some three-score-and-six years had attained to some degree of discretion as to her own affairs, and one would naturally suppose that in refusing an eligible offer to take such a daughter, the parents would exhibit either poor judgment or failing mental powers to an alarming extent.

Dr. L. W. Pendleton, of Portland, responded for "The Portland School for Medical Instruction;" Dr. D. A. Robinson, of Bangor, for "The Alumni;" and Dr. I. T. Dana, of Portland, for "The Maine Medical Association."

The Association then adjourned.

The day was otherwise occupied by various class reunions, and the exhibition at the Medical School building of a new and beautiful collection of plaster casts of the viscera and frozen sections of the human body, just imported by Prof. Gerrish from Leipsic.

Brunswick, Me., June 23, 1886.

NEW INVENTIONS.

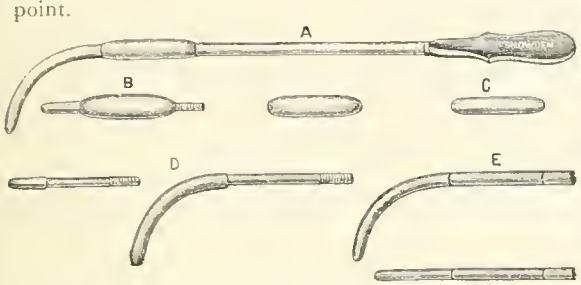
A DESCRIPTION OF A FULL SET OF POCKET BOUGIES MADE OF STEEL.

By T. NEELY RHOADS, M.D.,
resident physician at the jefferson college hospital, philadelphia.

I have devised the following extemporaneous mode of making bougies, which presents some points of practical interest. I take an ordinary steel bougie, No. 16 (French) is preferable, and melt a little solder around it about two inches from the beak, allowing it to extend back two inches or more, whittling off the surplus solder with a pocket-knife, each end of the bulb being tapered. Each time the bougie is passed a little more solder may be added, smoothing it with fine sandpaper until the size required has been attained, and the stricture thoroughly dilated.

It afterwards occurred to me that these bulbs might be made of steel, with a hole through each, lengthwise, or that they could be slipped on the bougie or staff. Mr. Snowden subsequently made the instrument for me as represented in the accompanying cut, by the letter *A*, which shows the instrument adjusted ready for insertion. It consists of a No. 16 (French) bougie in two sections, screwed together with a No. 22 bulb in position. *D* represents the curved point of Fig. *A*, showing the shoulder against which the bulbs rest, and also the threads to be screwed into the staff. *B* represents a

straight point with a No. 35 bulb in position, also showing the threads to be screwed into the staff. *C* shows the bulb, and *E* a sheath or bulb, with a circumference exactly the same as that of the bougie used, and which can be used with either the straight or curved point.



Twenty bulbs constructed on this plan are equivalent to forty bougies, for, by using the curved point, twenty curved bougies can be made that will dilate a stricture in any part of the urethra, and by simply removing the curved point and adding the straight, twenty meatus bougies can be made, suitable for dilating strictures at or near the meatus of the male urethra, and all strictures in any part of the female urethra.

I have found that patients do not suffer nearly so much pain in having this instrument passed as with the ordinary bougies. This is due to the following causes: First, the meatus is generally the most sensitive part of the urethra, and is always the *smallest* normally; second, the bougie in general use is so constructed that it gradually increases from the point up, being one or two sizes larger at the handle than at the point, consequently a stricture four or five inches from the meatus will not receive as much stretching as the meatus by at least one size. By using the bulbous instrument, only the same size passes the meatus, and its passage may be effected so quickly as to be almost painless, and when the bulb gets to the stricture it may remain there a minute or so without keeping the meatus on the stretch. Another advantage of the instrument here described is its cheapness. A full set of ordinary curved bougies, say twenty, will cost at least twenty dollars, and will take a large, cumbersome box to hold them, and a similar full set of meatus bougies will cost nearly as much, and need a box more than half as large, so that to carry the two boxes a carriage is almost necessary, while with my device, a case containing twenty meatus and twenty curved bougies and several hard-rubber bulbous explorers can be carried in the inside coat pocket, and can also be carried into a patient's room without exciting remark, and can be made for at least half the cost of the others.

It might be well to have in the case an extra staff of larger size for hyperæsthetic urethras, and an extra point or two, also larger, for enlarged prostates. There are also other variations that might be added.

NEWS ITEMS.

Maine Medical Association.—At the thirty-fourth annual meeting of this Society, held at Portland on June 1st, 2d, and 3d, the following were elected officers for the ensuing year:

President.—J. B. Walker, M.D., of Thomaston.

Vice-Presidents.—F. C. Thayer, M.D., of Waterville; H. E. Hill, M.D., of Saco.

Permanent Secretary.—Charles D. Smith, M.D., of Portland.

Treasurer.—Aug. S. Thayer, M.D., of Portland.

Corresponding Secretary.—C. E. Williams, M.D., of Auburn.

The Home for Incurables, of Baltimore, has recently received a legacy of $5000, from a deceased friend of the institution. The Home was incorporated less than three years ago and now owns between $35,000 and $40,000, all of which has been raised by donations, subscriptions, and entertainments.

Willard Insane Asylum, the central asylum for chronic insane cases in New York State, and which has now more than eighteen hundred patients has reduced the per capita charge to the counties to $2.00 per week, thus supplying the best of care at a minimum cost to the taxpayer. The cottage plan of house construction is in vogue at Willard's.

A Legal Point of Medical Interest.—A writer in the *Medical Age* says that a judge in Big Rapids recently decided that a physician's knowledge is his stock in trade, his capital, and the courts have no more right to take it without extra compensation than to take provisions from a grocery without pay to feed a jury. He declined to compel an expert to testify. Possibly in this manner the question may be decided by the Supreme Court.

Massachusetts Board of Health.—The reörganized Board of Health of Massachusetts has elected Dr. S. W. Abbott Secretary, and Dr. H. P. Walcott, President.

Professor von Langenbeck, who has been nearly blind from cataract, has been operated on successfully by Dr. Pagenstecher in Wiesbaden.

Typhoid Fever in the United States.—About twenty-five thousand deaths from typhoid fever occur in this country annually, and this represents fully one hundred and fifty thousand cases of the disease. The hundred and twenty-five thousand persons who recover, lose six weeks out of their lives, and carry perhaps some vestiges of the fever's influence for years.

Regulation of Veterinary Medicine in New York.—The passage by the last legislature of the bill to regulate veterinary practice makes New York the first State to undertake this work. The law compels the registration of veterinarians at the county clerk's office, and makes it incumbent on those registering to have a diploma.

Honors to Dr. Oliver Wendell Holmes.—The honorary degree of Doctor of Laws has been conferred upon Dr. Holmes by the Universities of Edinburgh, Cambridge, and Oxford.

Dr. Holmes, amid a scene of great enthusiasm, was admitted to the degree of Doctor in Letters (*honoris causâ*) in the Senate House, Cambridge, on Thursday, June 17th. The orator, in introducing him, characterized him as one who combined enthusiasm for science with

distinction in literature, one who "Phœbo ante alios dilectus," had received more than one gift of Apollo, the gift of skill in the healing art, as well as the gifts of eloquence and soul. They had lately heard with pleasure that the writer, whose almost earliest poem was "The Last Leaf," had just announced the "First Opening of the New Portfolio." The well-known volumes of the breakfast-table series were alluded to in the following terms: "Novimus quanto lepore descripserit colloquia illa antemeridiana, symposia illa sobria et severa sed eadem festiva et faceta, in quibus totiens mutata persona, modo poeta, modo professor, modo princeps et arbiter loquendi, inter convivas suos regnat." In allusion to an anecdote lately current in Cambridge, respecting some English travellers, who had deliberately taken the *Autocrat* with them as the only literary resource during a long tour in a remote part of Norway, the orator continued: "Talibus libellis comitati, etiam Scandinaviæ solitudines tolerare possumus; talibus libellis edocti, vitæ humanæ societatem melius diligere discimus." He also referred to the fact that the day was the anniversary of the battle of Bunker's Hill, which was commemorated by a monument in the immediate neighborhood of the Transatlantic Cambridge. It was also the anniversary of the death of Addison, and the language of eulogy once applied to that writer might appropriately be transferred to Dr. Holmes: "Haud ignobili poetæ, in oratione soluta contexenda summo artifici, censori morum gravi sane sed et perjucundo, levioribus in argumentis subridenti suaviter, res etiam serias lepore quodam suo contingenti." Addison, however, died in the forty-seventh year of his age, whereas Dr. Holmes was nearly fifty when his fame as a writer burst out into a fresh brightness like that of the Indian summer: "ubi in ipso autumno novus refulget æstatis splendor." The orator concluded in these words: "Videor mihi vatem quendam canentem audivisse, illum cujus in corde æstas æterna floreret, non vocandum esse senem. Equidem juventutis perpetuæ fontem illum quem trans æquor Atlanticum, Hispanorum nautæ frustra quærebant, nautam hunc felicioremn, non fabulosas inter insulas sed Academicæ juventutis in amore perpetuo, in amore mutuo, invenisse crediderim. Trans occidentis amplum illum sinum, levi phaselo vectus, diu naviget; nautili illius ritu, quem versibus tam pulchris descripsit, indies 'per ampliora ad altiora' tendat. Suam Academiam, per tot sæcula feliciter conservatam, intra paucos menses carmine sæculari iterum celebret, diuque superstes ipse exornet; nostræ denique Academiæ honoris causâ adscriptus, diu et nostrum et totius litterarum reipublicæ ad fructum floreat, vigeat, valeat, litterarum doctor, Oliver Wendell Holmes."—*British Medical Journal*, June 26, 1886.

Medical Knights Bachelor.—The honor of Knight Bachelor has been conferred by the Queen upon the following gentlemen: Surgeon-General T. Longmore, Professor of Military Surgery, Netley Hospital, Dr. E. H. Sieveking, Mr. W. White Cooper, and Dr. Douglas Maclagan, Professor of Medical Jurisprudence in the University of Edinburgh.

Dr. Gudden, who lost his life in an effort to rescue King Ludwig, of Bavaria, from drowning, was a man well known to students of medicine by reason of his contributions to science. He originated a new method of research known as the "atrophy method," which has been of great service in elucidating the difficult problems of brain anatomy.

The Department of Medicine of the University of Vienna has had a steady increase in the number of its medical students since 1878, until in 1885–86 the number was 2673.

Quain's Dictionary of Medicine is about to be translated into Italian by Dr. Tamburini, of Milan.

The Buffalo General Hospital has lately had a bequest of $20,000 from the late Francis W. Tracy.

Death of Melsens.—The distinguished chemist, M. Melsens, has just died in his seventy-second year. He was the author of the cure of mercurial and lead poisoning by the administration of iodide of potassium, and other important discoveries.

Honors to a Dentist.—The Queen has conferred the honor of knighthood on Mr. John Tomes in recognition of his eminent services to the profession of dentistry.

Medical Nonagenarians.—The deaths of two venerable members of the medical profession in Ireland have recently occurred. On June 2, Dr. James Apjohn, lately Professor of Chemistry in the University of Dublin, and for many years representative of that University in the General Medical Council, died at the age of ninety-one; and, also in June, Dr. Richard Grattan, senior Fellow of the King and Queen's College of Physicians in Ireland died in his ninety-eighth year.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING JULY 3, 1886.

Green, E. H., *Passed Assistant Surgeon.*—Ordered to Naval Laboratory at Brooklyn, temporary duty.

Brown, J. M., *Medical Director.*—Member of Retiring and Examining Board.

Ogden, F. N., *Assistant Surgeon.*—Ordered to "Juniata."

Siegfried, C. A., *Surgeon.*—Three months' leave abroad.

Hall, J. H. H., *Passed Assistant Surgeon.*—Detached from Museum of Hygiene, ordered to Naval Asylum at Brooklyn.

Wentworth, A. R., *Assistant Surgeon.*—Detached from "St. Louis," and ordered to "Brooklyn."

Decker, Corbin J., *Assistant Surgeon.*—Ordered to "St. Louis."

Berryhill, T. O., *Assistant Surgeon.*—Ordered to Museum of Hygiene.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM JUNE 29 TO JULY 3, 1886.

PROMOTIONS.

Brown, Joseph B., *Lieutenant-Colonel and Surgeon*.—To be Surgeon, with the rank of Colonel, Jan. 24, 1886.—*Circular A. G. O.*, June 28, 1886.

Heger, Anthony, *Major and Surgeon.*—To be Surgeon, with the rank of Lieutenant-Colonel, Jan. 24, 1886.—*Circular A. G. O.*, June 28, 1886.

Vickery, Richard S., *Major and Surgeon.*—Assigned to duty as Surgeon, in charge of Army and Navy General Hospital at Hot Springs, Arkansas.—*S. O. 150, A. G. O.*, June 30, 1886.

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. XLIX. SATURDAY, JULY 17, 1886. No. 3.

ORIGINAL LECTURES.

THE OPPOSITION TO EXPERIMENTS ON ANIMALS.

Extract from the annual oration "Impediments to the Progress of American Surgery," delivered before the Academy of Surgery of Philadelphia, January 4, 1886.

BY R. J. LEVIS M.D.,
SURGEON TO THE PENNSYLVANIA HOSPITAL.

GENTLEMEN: Whilst government aid is withheld from aiding surgical progress, legislation is being actively sought actually to hinder scientific investigation in certain directions. I believe that experiments on the lower animals are essential to the advancement of the science and art of surgery. The resolution adopted by the International Medical Congress of 1881, the largest and most widely representative assembly of medical men the world has ever seen, was: "That this Congress records its conviction that experiments on living animals have proved of the utmost service to medicine in the past, and are indispensable to its future progress. That, accordingly, while strongly deprecating the infliction of unnecessary pain, it is of opinion, alike in the interest of men and animals, that it is not desirable to restrict competent persons in the performance of such experiments." Such men as Virchow, Owen, Huxley, Carpenter, Paget, and Pasteur, have affirmed that "the remarkable advance in medical science and art, during the last twenty years, is due to experiments on the lower animals.

In reviewing the fanatical opposition to physiological experiments on animals it is evident that medicine is a shining mark for the shafts of detraction. A return, recently published, for the year 1883, showed that such experiments were performed in England, Scotland, and Ireland by only thirty-six persons. The inspector's report presents the conclusion that "the amount of direct or indirect suffering from the performance of physiological experiments during the past year was wholly insignificant, and limited to about fourteen or fifteen animals." Dr. Yeo, of King's College, London, says that "we learn from the reports that in 100 vivisections we should find the following numbers arranged to show the amount of pain inflicted:"

Absolutely painless	75
As painful as vaccination	20
As painful as the healing of a wound .	4
As painful as a surgical operation . .	1

No experiments that would cause pain were performed without anæsthesia, excepting a few hypodermatic injections or inoculations with morbid matter, and which were not more severe than a slight needle puncture or a simple vaccination. And yet this well-guarded and humane work has in Great Britain, met with the most vicious misrepresentation and fanatical abuse, and even its absolute and total prohibition is demanded.

It is evident that the fanatical tirade against physiological experiments on the lower animals is simply a Quixotic fight against a word, a name—the unfortunate and often misapplied word, vivisection. The word seems to be used generically to include every physiological experiment that may be performed on an animal, even the simplest and absolutely painless.

A speaker at a recent meeting of the American Society for the Restriction of Vivisection, defined vivisection to be, "the cutting, flaying, pinching, burning, crushing, tearing, bleeding, disembowelling, maiming, and eviscerating generally of living animals." A writer on the subject says: "The very word vivisection is sharp. It is smooth and highly polished, with a keen cutting edge. It tells of a helpless, suffering creature under the steady hand of a pitiless dissector. The skin is flayed away, the quivering flesh carved off, the nerve-trunk pierced with needles, the bare bone sawed asunder. The cries of bitter agony are unheard by the stern operator; the resisting struggles have been foreseen and forestalled. The ghastly work goes steadily on, until, after a while, the silver cord is loosed and the golden bowl broken, and then, at last, all is silent and still."

The disordered brain of another fanatic describes vivisection "as sawing across the back bone, dissecting and irritating the great nerves, driving catheters along the veins and arteries, inoculating with dreadful diseases, cutting out parts of the intestines, stewing and baking in a stove, pouring boiling water into the stomach, boiling or freezing to death, and by mechanical processes reducing the brain to the condition of a recently ploughed potato field." Another violent opponent asserts that one eminent medical authority disapproves of the use of anæsthetics because "an experiment is made more satisfactory when the animal exhibits signs of pain." Cardinal Manning gives the opinionated statement that experimenting on animals "is a detestable practice, not attended with any scientific results;" and Chief Justice Coleridge dogmatically asserts that "the practice is displeasing to Almighty God."

At the meeting referred to, of the American Anti-vivisection Society, one, said to be a medical man, communicated his views by saying that, "unrestricted vivisection should only be tolerated in a community of devils." A speaker at the meeting made the exaggerated statement that "thousands of animals are yearly sacrificed in order to show to students what is stated in their text-books is true." A medical speaker next said, referring to a case of severe illness in his own family, "that vivisectors are less capable of managing such diseases than ordinary intelligent physicians . . . . visionary in their ideas, prejudiced in their aims, and illogical in their conclusions." Another medical speaker said, "the argument of the vivisectionist is that he learns to save men by flaying and disembowelling brutes. An experiment," he said, "is to thrust a trocar into an animal's heart, causing the blood to spurt five

or ten feet, and the students are asked to notice how far the action of the heart expels blood." And this same speaker, who tells us of the fondness of medical men for all this brutality, gives us to understand that their bloodthirstiness is not limited to the sufferings of brutes. He says, "the amphitheatre of my own lecture-room is crowded whenever I have to perform a surgical operation which covers the floor with blood for an hour or two; but when I bring all the resources of what I have been able to gain from a life of study, that would do away with the necessity for such an operation, I find that the amphitheatre is about half filled. Let it be known that a surgeon is going to cut some poor sufferer for a couple of hours, and an operating room is crowded."

With such inflammatory and specious trash is the fanatical flame fed, and the noblest and most humane of all human occupations is insulted and traduced. Truly, detraction does love a shining mark!

It is to be regretted that the most of the sensational misrepresentations in regard to experiments on animals have been spread before the community by members of the medical profession. From the most insensate indifference to the unnecessary sufferings of animals everywhere about us, merely for the sake of our pleasures or caprices, the community has had its tenderest and most humane sympathies aroused to a hyperæsthetic pitch.

Among the sympathizing audience at the meeting referred to, whose hearts were in such anguish, horror-stricken at the recital of medical atrocities, sat some with feathery decorations, to yield which many birds had been painfully slaughtered, or from whose living and bleeding bodies the plumage had been torn. The night of meeting was midwinter, and many fur-bearing animals that had died by gunshot wounds or had perished after struggling for life, in traps, contributed their pelts for the sake of comfort or fashion. But all this unheeded suffering, at the price of blood, was inflicted far away, and it mattered not, for the wearers had nothing to do with it. Perhaps some of the sympathizers with brute suffering had been at dinner "with good capon-lined," and, after being drawn homeward by emasculated equines, would sup on terrapins that had met death in its most horrible form, by the customary practice of scalding. But this is only an every-day, household practice of vivisection by the cook, and not by the doctors; and so neither societies nor legislation are required for prevention.

Whilst on this subject, it occurs to me to quote Sir Henry Thompson's comments in regard to the popular vivisection of the Strasburg goose, with its feet fastened to a board near a fire, and stuffed until its hypertrophied and fat-degenerated liver becomes a luscious morsel for the "pâté de fois." He says, "I would strongly commend the condition of these poor brutes to the consideration of the antivivisection society, since more disease is produced among them, in order to furnish our tables with the 'pâté,' than by all the physiologists in Europe, who in the interests, not of the human palate, but of human progress, as effected by therapeutic knowledge, sometimes propagate and observe certain unknown forms of disease amongst a few of the lower animals."

It is admitted that in experimental investigations, performed on the lower animals, the infliction of pain may in a few and rare instances, be unavoidable; but it seems remarkable that those few cases should attract so much exclusive sympathy whilst millions of instances of the most relentless and unnecessary cruelty continue to be inflicted without an appeal from humanity. No cruelty practised elsewhere throughout the world equals the sufferings of cattle in the winter season in our Western States and Territories. A writer in a recent agricultural journal says: "Cruelty to animals in the city of New York, in its extent and enormity, compares with cruelty to animals in the great West as an infant's breath compares with an Arctic blizzard. Millions on millions of cattle, warm-blooded, sensitive—that jump at the prick of a pin—are turned out by the remorseless owners to gather scant herbage where snows and frosts and fierce winds make life a protracted agony. Does anybody doubt that domestic animals suffer intense pain when exposed, without protection, to an atmosphere five to fifty degrees below zero? In those regions hundreds of thousands are turned loose without shelter and without food, except such as they can gather in the frosts and snows and fierce winds that torture and often terminate the lives of men and beasts. They have buffeted the storms of this terrible winter, and now, with sunken eyes and bended backs and protuberant bones, are lying down to sleep their last sleep, and have passed through the intensest agony animal life is capable of."

"Let the same protracted suffering, the same degree of torture be inflicted by some new process, some unaccustomed method, and we would denounce it with one accord. If cattle never had been forced by cruel owners to gather their living where a decent living could not be found; if never before had they been compelled to make their beds in snow, when the thermometer was below zero, and the wind like a scourge of thorns, the first man who deliberately put them to that torture would be pronounced a 'monster of cruelty.' The birds which go south in winter, and the buffalo that migrates to milder regions as cold weather comes on, are far wiser than the herdsmen who force their stock to buffet the almost arctic winter, preventing them from wandering to milder climates if they could."

Mr. John Bright, of England, is authority for the statement that sixty thousand camels perished by starvation and suffering during one of the Afghan wars. It is estimated that half a million of pigeons are yearly shot from traps in Great Britain for the sake of mere sport. Whilst in southern Florida, last spring, I met a professional bird hunter who had recently sent to a northern market the ornamental plumages of nine thousand birds, and during a number of previous years accomplished about the same—an enormous vivisection for Fashion's sake!

So the enormous cruelties to animals, by exposure, goading to labor, branding, castrating, plucking of feathers, stuffing to produce disease, and painful methods of slaughter, continue without attracting more than very slight attention.

Such vast cruelty that is passed by with disregard and apathy, when contrasted with the intense sympathy for the occasional suffering of an animal, inflicted in a humane cause, impresses one with a curious antithesis that exists in human nature. The collective commission of extreme sins by great numbers is overlooked, whilst

a small transgression by one individual meets with universal execration. The collective homicides of war are applauded as but attractive romance, whilst only single-handed murder is properly abhorred.

In an address on vivisection, Dr. Keen, one of the Fellows of this Academy, well said, "To grow better, we must try new methods, give new drugs, perform new operations, or perform old ones in new ways; that is to say, we must make experiments. To these experiments there must be a beginning; they must be tried first on some living body, for it is often forgotten that the dead body can only teach manual dexterity. They must be tried either on an animal or on *you*. Which shall it be? In many cases, of course, it is perfectly legitimate to test probable improvements on man first, although one of the greatest and most frequent charges against us doctors is that we are experimenting upon our patients.

"But in many cases they involve great risk to life and health. Here they cannot, nay, they must not, be tested first upon man. Must we, then, absolutely forego them, no matter how much promise for life and health and happiness they possess? If not, the only alternative we have is to try them on the lower animals; and we would be most unwise, nay, more, we would be cruel, cruel both to man and to animals, if we refused to pain, or even to slay a few animals, that thousands, both of men and animals, might live."

"Who would think it right to put a few drops of the hydrochlorate of cocaine, a year ago almost an unknown drug, into the eye of a man, not knowing what inflammation, or even loss of sight, might follow? Had one dared to do it, and had the result been disastrous, would not the law have held him guilty, and punished him severely? But so did Christison with Calabar bean, and well-nigh lost his own life. So did Toynbee with prussic acid, and was found dead in his laboratory." The wonderful and unique properties of cocaine were first tested on animals, and its beneficent application to human suffering soon followed.

We cannot believe that all those totally opposed to experiments on animals have the wicked intent of stopping all surgical progress, but some would simply prefer that the investigations should be made on human beings—of course, on others than themselves. To such, the recent earnest proposition to utilize condemned criminals for cholera experiments should find a congenial response. The *Indian Medical Gazette*, of last September, states that from three hundred to four hundred persons in India are judicially sentenced, every year, to suffer death; that, taking one day with another, not a day passes without the execution of one individual. So the material for human vivisection is abundant, and ready to present itself voluntarily, as commutation of the death sentence is proposed to the victims who may be so fortunate as to recover.

As to the oft-repeated assertion that nothing has been gained to science or to humanity by experiments on animals, it cannot be denied that to such manner of investigating is due our knowledge of the means of relieving human suffering by some of the most valuable anæsthetics and by hypodermatic injection; and so, also, has been discovered the action of most of the new remedies that have been added in the last twenty years, such as chloral, nitrite of amyl, nitro-glycerine, iodoform, eserine, caffeine, jaborandi, paraldehyde, antipyrin, and cocaine.

So far as legislative restriction of experiments on animals is concerned, I believe that the members of the medical profession need no legal restraint, and that the matter may well be left to their humanity and honesty of purpose. If experiments on animals should be performed by improper persons, wantonly and without scientific and humane objects, then the existing statutes against inflicting cruelty are all-sufficient.

If legislative restriction were really needed to satisfy sentimentalism, the bill, as presented at the last session of the Pennsylvania Legislature, is not, in its provisions, objectionable; and there was a general consent to the bill by those in the profession who take the greatest scientific interest in its subjects. But it was distinctly understood that this consent was with the agreement that further agitation of the subject should end with the passage of the bill. To this the advocates of the measure would not consent, and it is evident that they intend to continue to agitate and appeal for the absolute prohibition of experiments on animals. The same unsatisfied and violent opposition continues to exist in England since the final adoption of the laws on the subject.

A CONTRIBUTION TO THE STUDY OF HAY FEVER (SO-CALLED).[1]

BY BEVERLEY ROBINSON, M.D.,
OF NEW YORK.

THE pendulum never swings in one direction too far, unless it goes out of the way in the opposite direction almost to an equal extent. As applied to our appreciation of the real nature and correct treatment of so-called hay fever, this statement is specially illustrative, and as true as any dogmatic affirmation can be in matters medical.

Not very long ago, scarcely anyone thought of a different etiology of the painful periodic paroxysmal attacks of sneezing, coughing, and dyspnœa characterizing this disease from that which inheres in the vitalized pollen granule of flowering plants and grasses. At present this external irritant is regarded by the most advanced workers in rhinology merely as one of many local excitants, and among these as possibly by no means the most active. Changes of temperature, of light, of winds, of electricity and barometric pressure, are said equally to hold a determining influence in bringing on these attacks. Yet none of these external agents is sufficient to produce hay fever, unless there also be present a highly excitable vasomotor centre. This nervous centre may have become diseased primarily, so that the slightest direct or reflected irritation, whether it be from an external agent, bodily disease, or psychical impression, may be sufficient to render it unduly excitable, and thus give rise to the combined symptoms of hay fever. Numerous experts, however, have now come to regard the main source of this disease as being in the nasal fossæ. Normally, as

[1] Read before the Section of Laryngology and Rhinology of the New York Academy of Medicine, Jan. 22, 1886.

we know, these passages are irritable; but this degree of sensitiveness is inadequate to cause attacks of hay fever, something more is required. There should be at least a hyperæsthetic condition of the pituitary membrane, or marked morbid changes under or about it should be present. From this standpoint, the whole category of nasal affections has been gone through with before one has finished counting proximate causes of hay fever. This ultra view would not be so objectionable were it not that the immediate consequences to *noses* are disastrous. Everyone is seized with an inordinate desire to operate, and whenever hay fever victimizes a patient, a deviation of the septum, or the slightest turgescence of the turbinated bodies, is immediately shown to be the origin of the trouble, and forthwith radical measures are adopted to rid the patient of structures which are often in reality inoffensive. True it is, however, that an individual frequently does suffer from an intra-nasal condition, which at a given stage is undoubtedly a most important factor in the production of paroxysms of hay fever. Of this fact there can be no contention at the present time, if due consideration be given to the numerous and convincing reports of competent observers. Yet, and perhaps more for this reason than another, it behooves every specialist to be watchful, and *not* willingly to admit that there is no hay fever, unless there be pronounced nasal disease, and that by nasal treatment *solely* this disease can always be obviated or arrested. Already I have seen more than one case which has convinced me how incomplete and erroneous such a view certainly is, and as a further study of this disease I would direct attention to the following facts and remarks:

First. A patient of mine who had had during several years repeated attacks of hay fever, accompanied by conjunctivitis, sneezing, asthma, etc., was affected last summer in a similar manner, about the same period as usual. After these annual attacks had subsided, and until the following year at the same date, my patient had no symptoms of nasal disorder, or of other bodily disease which predisposed her to hay fever, either by direct or reflex irritation. Upon reviewing her history carefully, her attacks were shown to be brought on on each occasion by rapid and considerable changes in the temperature and moisture of the ambient atmosphere.

Second. A gentleman is now under my care who has nearly complete occlusion of both nasal passages, evidently occasioned by hypertrophy of the turbinated bodies, and particularly of the posterior portions of the lower bodies. Until one year ago, and during many previous years, at which time his nasal passages were only partially obstructed by reason of hypertrophic enlargement of the turbinated bodies, there were annual attacks of hay fever. At present, when his nasal passages are almost impervious to air, a great portion of the time the hay fever attacks have entirely disappeared. If the sensitive area of J. H. Mackenzie were in this instance at fault—*i. e.*, the posterior part of the septum and lower turbinated bodies—the attacks of hay fever would probably have persisted and not completely stopped as they have. If Harrison Allen's doctrine that occlusion of the nasal passages is the secret of such attacks can be sustained in many examples, in this one it proves to be insufficient at an advanced stage of the disease to explain the absence of an important series of symptoms. Add to the case referred to by me, two cases reported by Sommerbrodt, in which turbinated hypertrophy existed and the galvanocautery was applied locally in a thorough manner. Despite this operative procedure, the attacks of hay fever occurred with their usual severity.

Third. Nasal polyps may or may not be found in patients who are sufferers from hay fever. When they are present, their removal has frequently been followed by relief from painful recurring paroxysms of this disease. In a number of cases, one of which has come under my notice, the polyps were radically removed without, to any apparent degree, influencing advantageously the return of attacks of an analogous kind either as regards their intensity or frequency. In my case cough and dyspnœa at least were evidently more nearly dependent on a fibroid condition of the lungs and dilated air cells, than they were on a previous condition of nasal obstruction occasioned by polyps. Indeed, the case was really one of bronchitic asthma and emphysema, and not of hay fever. And here it is worth noting what I have certainly observed more than once, that sufferers from bronchitic asthma are also affected at times with a marked degree of nasal obstruction due to nasal catarrh, thickening of the septum, or some other morbid state of the nasal passages. The attack of asthma in these cases frequently begins in the nose and works its way downward until, within a few hours, the constant sneezing, inability to draw air through the nose, watery congested conjunctiva, and contracted bronchi, accompanied by noisy stertorous respiration, approximate them closely with those who are true victims of hay fever. So far as mere symptoms of disease are concerned, how such cases can be distinctly separated from examples of hay fever, I should be unable to say. Of course, when an accurate physical examination is made, the intrapleural and pulmonary conditions are such that we are no longer permitted to doubt as to the true pathogeny of the disease we are called upon to treat. And in the treatment itself we also find verification of our diagnosis, since remedies which remain with little or no effect upon the thoracic dyspnœa of hay fever are of great utility in allaying this symptom even though considerable and chronic structural changes be shown to exist within the thorax. I am glad to note that a distinguished English authority, Sir Andrew Clarke, in the January number of the *American Journal of the Medical Sciences*, points to a view which I have for some time distinctly held—*i. e.*, the close relationship between these two forms of disease. In a series of propositions this author sets forth what he regards as the teaching of a study of hay fever, concerning the pathology of bronchial asthma, holding that it is a neuro-vascular trophic disease, and has its origin in a special vulnerability of the respiratory mucous membrane, of the respiratory nerve centres, and of certain portions of the sympathetic. So it is doubtless in just such instances that we should appreciate how uncertain, and even useless at times,

mere local treatment of the nasal passages will become. Even the galvanocautery cannot be expected to reach the primary source of disease, as the "roots of special vulnerability" are in the bronchial tubes, not in the nose itself. My experience, I am much gratified to find, is in accord with that of Da Costa (MEDICAL NEWS, March 9, 1885), Cohen (*American Journal of the Medical Sciences*, Jan. 1885, p. 309), and others. In severe cases of hay fever the asthmatobronchitic manifestations are often unrelieved or but slightly modified by the local use of cocaine, despite the allaying of pruritus, or the *temporary* reduction, at times, of nasal intumescence.

Fourth. In the very large number of nasal affections which are seen in our clinics for treatment of this class of cases, the proportion of those who have had attacks of typical hay fever is relatively small. If this statement be admitted, and it cannot be seriously questioned by anyone who is really familiar with facts of this nature, it is obvious that the morbid intranasal condition is only efficient as a factor in producing hay fever when a predisposition exists which enables certain exciting agents to produce the malady in one class of persons, and yet entirely fails to produce it in others. Again, that these exciting agents are in a remarkable manner *specialized*, seems also proved, since emanations which in one person provoke a severe attack, produce in another, liable to hay fever, no sensible effect. The association of ideas may also awaken a paroxysm of vasomotor coryza, as we find an example in a case of "the production of so-called 'rose cold,' by means of an artificial rose," lately reported by Dr. John H. Mackenzie,[1] of Baltimore. In this, and other somewhat analogous cases, in order to produce such a result there must probably be "a deranged mental impressibility," in addition to an irritable condition of the turbinated bodies. Yet, despite these statements, it is now clearly determined, and widely recognized, by many careful, expert physicians that at or about a certain period of each year these attacks are sure to take place with some individuals, unless they have been submitted previously to suitable local treatment of their nasal passages. Even to this category, however, there are some exceptions, for, as it has already been stated, a few hay fever patients have proved to be wholly refractory to this local treatment, and their paroxysmal attacks have recurred as before, unless they have banished themselves for a time to a particular locality among the mountains, or at the seashore.

Of these two classes of sufferers, we can truly say, the first undoubtedly have nasal disease of some kind, and that the others are entirely free from it in any form, or are affected by it in such a way that we cannot determine its existence by our usual methods of examination. That the first class should be treated systematically for nasal disease is rational and judicious, and owing to wise treatment such benefit will frequently result that they are completely cured, so that they can expose themselves with absolute impunity to all causes which formerly occasioned their attacks. In the second class, continued or energetic treatment of the nose is irrational and should not be carried on, unless it can be reasonably shown that the nerves of the pituitary membrane may be morbidly altered despite our ability to affirm the change except through proper deduction from knowledge of the course and results of treatment in analogous affections of adjacent organs, the structure of which is not unlike. This being admitted, my explanation may now be offered: I do not believe that previous to the time of the attack of hay fever a *morbid intranasal condition*, recognizable by our explorative tests, is invariably present. Yet I am of the opinion that, even in these instances, morbid changes affecting the peripheral nerves may be responsible for the occurrence of symptoms of the disease. These morbid changes I assume to be in their nature *neuropathic*. They are probably inflammatory at times, and not less frequently are, doubtless, such as characterize atrophy of the nerves, or a thickening of their sheaths. I can appreciate the objections which will be immediately urged against this view. What proof have you? In reply I would say, I have just the same degree and kind of proof that I possess for the existence of many neural diseases elsewhere situated. Direct pathological proof, such as the microscope alone can ordinarily afford, I have not. But proof sufficient from the close study of the disease, belongs to me as to others. And this, in the interpretation of hay fever, must be for the while satisfactory, since it is all we have hitherto acquired. In the class of cases to which I refer we can appreciate how there may be hypersensitive areas distributed more or less widely over the pituitary membrane. These sensitive points may then be readily distinguished by contact with a probe or other foreign body. Inasmuch, however, as *irritable areas* cannot *invariably* be discovered in advance of an attack of hay fever (and this statement is the expression of my own clinical investigation), and other sufficient evidences of a determining intranasal causation of these paroxysms are not present (unless my view be adopted), it is logical to infer that if the nasal condition is really the efficient and primary cause of the attacks, it must be owing to an obscure neuropathy (translation of our ignorance) which merely renders the peripheral nerves sensitive to *special* irritants, and yet is only a functional disturbance. The symptomatic condition referred to is, moreover, not unlike one that often occurs in the pharynx, and which I interpret in nearly the same way that I explain some phenomena connected with hay fever.

At present, for example, an adult patient is under my care, in whom the sensation of pharyngeal pains is felt only during the time *cold* air is respired. Pressure, moderate in force, speech, song, deglutition, etc., do not occasion any unpleasant sensations whatever. It is to a certain degree appreciable, therefore, reasoning from analogy, that a paroxysm of hay fever may be induced by very many external irritants, which act primarily through contact with the pituitary membrane, although the proof we discover of nasal disease is limited to (1) the obvious effects of external agents of various kinds; (2) the results derived from the use of topical treatment. If this belief be accepted, it can be easily understood

[1] American Journal of the Medical Sciences, Jan. 1886, p. 57.

that, according to the cause of the attack and the nature of the peripheral nerve changes in the nose, either a local anæsthetic, like cocaine, an alterative, like iron, a mild chemical cauterizing agent, like carbolic acid (as I have elsewhere stated), or the galvanocautery may each or all prove sufficient to bring the attack to a rapid close, if it have already begun, or prevent its occurrence when applied in advance, and in view of the local conditions we are required to treat. The relative utility of the different local agents just mentioned will frequently depend on the nature and situation of the pathological changes in the nose, as well as on the degree to which, if any, they are accountable for the hay fever attacks. In this connection I would cite the judicious remarks of J. Solis Cohen, who, after alluding to the different means employed in removing morbid intranasal conditions, says, "Destruction, however, is not cure, and the production of unnecessary cicatrices may prepare the ground for less benign disease in the future. While instances of permanent relief by these methods are sufficiently numerous, the fact cannot be ignored that cases of *reported cure* are sometimes compelled to seek treatment for recurrence. The choice between reliance upon a satisfactory palliative or resort to operative interference in the chance of permanent relief must be settled between patient and physician" (*American Journal of the Medical Sciences*, Jan. 1885, p. 310). I believe, however, that we have no agent so generally useful as the electrocautery in alleviating or curing cases of hay fever of nasal origin; yet there are cases, especially those of bony obstruction, to which it is altogether inapplicable. In view of a case of intense paroxysmal sneezing, which had lasted for several years, and was probably dependent on, and certainly allied with, a complete obstruction of one nasal passage, mainly by deviation of the cartilaginous septum, and because in this case I made a successful use of the galvanocautery, I am now disposed to include such cases among those occasionally suitable for this treatment. The galvanocautery is, of course, particularly indicated in all instances of considerable or complete occlusion occasioned by hypertrophy of the intranasal soft parts. While I commend the galvanocautery thoroughly in almost all *these* cases, and regard it as greatly preferable in ease of application and subsequent beneficial results to the use of the cold wire snare, I continue to believe that in less aggravated forms of obstructive disease, the hay fever paroxysms may be almost equally well treated by such means as pure carbolic acid or chromic acid. In favor of the primary trial of these agents may be mentioned the facility with which they can be employed, and their less destructive action.

Fifth. Before recognizing the dominant influence of intranasal conditions in determining hay fever attacks, it is essential to question the patient closely, and endeavor to discover if there be any other local or systemic disorder present, which might render doubtful the accuracy of the diagnosis. Of course, if any such disease be found it must first be carefully treated, and until it is fully eliminated in this, or some other manner, as an efficient factor in causing hay fever attacks, we cannot properly estimate the direct power in this direction of the morbid intranasal conditions.

Sixth. In this view, that remarkable protean nervous disorder—central vasomotor disease—should not be overlooked, although our ability precisely to locate it is frequently insufficient. These nervous centres have played an important though exaggerated *rôle* in the physiological interpretation of diseased action during the past ten years or more, and no doubt, partly on this account, many persons are sceptical as regards their influence, whenever it is now alluded to. I am disposed to believe, however, that their control in this disease will always be notable in a considerable proportion of cases, although the extent to which it is exercised is not yet clearly and entirely appreciated in every instance. When, however, it is recognized as being present, it will usually be correct to state that, in these instances, mild topical applications to the nose for the purpose of aborting or preventing attacks of hay fever will prove almost useless. Even though this be true, there will still remain a few among these examples, in which cauterization by means of the galvanocautery, will be curative where the previous means have proved inadequate The full explanation of this fact is doubtless that the cautery reaches and destroys more thoroughly all the morbid tissues and thus abolishes receptivity through the nose, of irritation from numerous foreign substances which previously had acted as excitants of an impressionable nerve centre directly related to the olfactory organ. Of course, when the excitant is purely a psychical condition of which the resultant, so to speak, in a physical way, is the temporary engorgement of the turbinated bodies which gives rise to the different rational symptoms of hay fever, all local medication is to a great extent delusive and unsatisfactory, and at best only palliative.

To sum up this brief paper in reference to hay fever (so-called), I wish to add that I had a single purpose before me in writing it, and that purpose was simply to prevent, if possible, the present current of medical opinion carrying us too far in a right direction, and making us regard every sufferer from hay fever as a case either for somewhat severe nasal operation or continued nasal treatment. Many there are amongst these unfortunates who have no specially sensitive areas to cauterize, no occlusions to destroy, no abnormal septa to cut away, no catarrh to treat. They are simply individuals who, unless evident pathological conditions betray the origin or source of far-removed nasal and other phenomena included in the term hay fever, are still for me obscure neurotics or neuropaths, or those who are *specially* influenced by pollen granules, or by *one* or *more* of a vast number of emotional or psychical influences, external irritants, or *atmospheric conditions*. Nor do I consider it a *retrograde movement* at this time to make such a statement, but rather the act of throwing called-for *weights* into one side of a balance to make *equipoise*, when almost all late observers have been contending in favor of a sound but, in my judgment, too exclusive theory, which is insufficient to explain all cases of hay fever satisfactorily.

THE MORTALITY OF THE CÆSAREAN SECTION,

WHEN THE CONDITION OF THE SUBJECT IS FAVORABLE, AND WHERE THE UTERINE WOUND IS SUTURED SO AS TO RENDER IT IMPERVIOUS TO FLUID, AND TO SECURE AN EARLY UNION OF ITS SEROUS COAT.

BY ROBERT P. HARRIS, A.M., M.D.,
OF PHILADELPHIA

IN the last American edition of Playfair's *Midwifery*, prepared a little more than a year ago, will be found the following under the heading of "Possibilities of Gastro-hysterotomy:" "Old as it is, the Cæsarean operation is still upon trial, and has by no means attained the minimum mortality of which it is capable under modern improvements as one of the forms of abdominal surgery." When this was written the new method of uterine closure, devised by Dr. Sänger, of Leipzig, was just beginning to attract attention, and it was known to the writer that Dr. Leopold, of Dresden, had operated three times by this plan, with entire success to mother and child. What I then hoped for by this improvement has been more than realized in the Maternity Hospitals of Germany, and I now have the pleasure of presenting a tabular record of sufficient extent to warrant the claim that the old operation performed in good season and with careful uterine closure is by no means "the most dangerous operation in surgery," as was once claimed by a prominent gynecologist before the American Gynecological Society; but is even less fatal than craniotomy in badly contracted pelves. In view of this German record, we cannot endorse the recently expressed claim of Mr. Lawson Tait, that the Cæsarean operation has a mortality of over 99 per cent., and that the hope of the future is in the comparatively safe method of Professor Porro.[1] Thus far there is no general or hospital record in any country to compare with the one herein given. Under the first 28 Porro operations, 18 women were lost, although all but 5 of the children were alive at delivery; and under the first 28 of the second hundred, 16 women and all of the children but 6 were saved; against which we place the saving of 19 women and 24 children out of the first 28 Sänger cases at home and abroad. The best Porro record in any European maternity is that of Milan, where cases 1, 2, and 9 were fatal in a list of 14, under five operators. Under three operators in Leipzig and two in Dresden, the Sänger method shows a record of 6 women and 6 children saved in one maternity by 6 operations, and 9 women out of 10 in the other, with all of the children. The whole record of Germany foots up 21 operations with a loss of 3 women and 1 child.

We are sorry not to be able to write more encouragingly about our own portion of the table, which is rather a dead weight upon the balance; but the fact is, that with but one exception, and that was a cancer case, the prior condition of the women gave the operators little or no hope of success. It is the old story here, try every possible obstetrical expedient first, and then "the forlorn hope" of the knife. Having adopted by degrees the British estimate of the dangers of the Cæsarean section, we have very naturally as the result of dreading its effects, increased our mortality almost to the English measure. This is shown by the changes in our statistical record. We have had, so far as known, 142 operations in the United States. Of the first 70, down to 1866, 37 resulted in the recovery of the women; and of the balance, 72, only 17 had a favorable result. Of the first 70 children, 35 were lost, and of the 72, 42 were found dead. Of the 70 there were 23 *timely* operations, saving 20 women and 20 children; and of the 72, only 10, undertaken early, saving but 3 women, although 9 of the children were extracted alive. By the increased mortality of the last twenty years, we have reduced the percentage results of timely operations from 75, or 21 saved out of 28, to $69\frac{2}{3}$, or 23 out of 33; and the general average of recoveries from $52\frac{6}{7}$ per cent, to a fraction over 38 per cent. It is quite time, therefore, that we should follow the example of the German rather than of the English operator.

In the Cæsarean operation we have really more to fear from the condition of the patient prior to the use of the knife than from the surgery *per se*, and in making a prognosis much will depend upon the answers to the following questions: 1. Is the woman a dwarf? 2. Are her powers of endurance below standard by reason of having been rachitic in childhood? 3. Has her strength been wasted by long-continued uterine action? 4. Has she been subjected to attempts at delivery by the forceps, turning or craniotomy? 5. Has the fœtus died from uterine pressure, and if dead, has it become putrid? 6. Has it been partially delivered by turning or decapitation? 7. Is the woman syphilitic? 8. Are her kidneys unsound, showing albumen or pus in her urine? 9. Has she a uterine or pelvic tumor? and 10. Has ergot been administered? If all of these can be answered in the negative, there is but comparatively little risk in the operation in the majority of cases.

Rachitic dwarfs very soon become exhausted by labor, and require for safety that the operation should be performed as soon as the os uteri is sufficiently open for drainage. Tumor cases are apt to end fatally, but there have been some very exceptional examples in the United States. Cases of impaction of the fœtus in the pelvis in healthy women have generally recovered in our country, even when the labor has been of long duration. This is to be accounted for by the robust condition of the subject and her normal powers of endurance.

The Sänger method of operating requires for success that the woman should be in a *favorable* condition, and that she should not by delay or futile expedients have lost her child. It requires on an average one and a quarter hours to perform the operation, most of this time being expended in securing the uterine wound against the possibility of leakage. This avoids one serious element of danger in the old operation, which depended largely for safety upon the continuance of uterine contraction; secondary inertia and gaping of the wound, often resulting in the escape of fluid into the abdominal cavity, and the consequent death of the patient.

Summary: German cases, 21. Women saved, 18 Children living, 20
American " 5. " " 0. " " 2
Austrian " 2. " " 1. " " 1

In the cases marked by a (*), the peritoneum was not separated from the edge of the uterine wound, but was simply slid over and welted in, when the sutures were inserted and tied.

Manual compression to check excessive hemorrhage when the uterus is incised, is another measure of safety in the improved operation. There can be no longer any doubt about the importance of suturing the uterine wound, and of using so many stitches that the parts will be securely held together without much individual strain upon the sutures.

The value of the Sänger method as simplified since its introduction will be shown by the fact that Germany has saved out of 21 women in six years, as many cases as have been saved under 75 operations in the United States in twenty-five years.

For a full account of the method of performing the Sänger operation, see the *American Journal of the Medical Sciences*, for October, 1885, page 365.

My investigations, which commenced in 1869, soon satisfied me that a great element in the production of fatality in the Cæsarean operation was fear of its consequences, and the consequent postponement of its performance until it was too late to hope for success in a large proportion of cases. In the early days of our country, there were many more *timely* operations and consequently a lower degree of mortality, but of later years the *scare* has become greater under the almost universal teaching of obstetrical writers and lecturers, and we have been reaping the fruits of it as shown by the fact that but 7 women recovered in the last decade, out of a total of 35, or exactly 20 per cent., and that 23 of the children were either dead or in a moribund state at delivery; we have now about reached the mortality of Great Britain, and ought to take active measures to "face about." Let the obstetrical professors in our colleges teach these facts to their classes, and the time will come when the operation deprived of its dangers shall have a much better reputation for safety. If up to twenty-five years ago we saved more than 50 per cent. of the women, we ought to do better than this under the safer methods of Germany. It is a great satisfaction to me to find that the views I have long held and contended for have been at last established by actual results.

In the opinion of Schauta, of Innsbruck, an important element of success in the Sänger operations has been the employment of silver wire as the material for the deep uterine sutures, in almost all of the successful cases. This secures the wound against gaping, as the material will not stretch. and is not inclined to cut into the tissues. The credit of first using silver for this purpose is due to the late Dr. Frank E. Polin, of Kentucky, whose successful operation was performed in December, 1852. Several women were subsequently saved by the same material, and one patient twice; but of latter years silk has almost entirely taken its place here, with a much higher rate of mortality as the apparent result. Suturing the uterine wound has become almost universal in the United States, but to very little purpose. There is no use in employing catgut—putting in silk stitches an inch apart—or very little in inserting them at all in the desperate cases in which they have generally been tried. As long as obstetrical lecturers will teach their students to use first the forceps, then try craniotomy, and in the event of failure to deliver by the Cæsarean section, in cases of marked pelvic obstruction, we must not hope for a moderate rate of mortality from the last expedient.

A CASE OF LYMPHADENOMA—HODGKIN'S DISEASE.

By GUY HINSDALE, M.D.,
of Philadelphia.

Dr. Hodgkin, of Guy's Hospital, first published, in 1832, in a paper entitled "Some Morbid Appearances of the Lymphatic Glands and Spleen,"[1] an accurate description of four cases of the disease which is now generally known by his name. This paper did not, until within the last ten years, attract very general notice. Dr. Wilks, however, in a paper read before the London Pathological Society in 1878, called especial attention to Dr. Hodgkin's paper, exhibited the original specimens preserved in Guy's Hospital Museum, and called the disease by Dr. Hodgkin's name.

In Dr. Wilks's paper there are records of a large number of cases reported by Greenfield, Gowers, Coupland, and others. Dr. James Hutchinson[2] has recorded a remarkable case of this disease, and a full table of the bibliography of the subject. Dr. William Osler has also treated the subject systematically in an article in Pepper's *System of Medicine*.

The case which I wish to record is as follows:

Lou. H., a German, aged thirty-five, was admitted to the Episcopal Hospital, Philadelphia, during the service of Dr. F. P. Henry, on June 14, 1882. He said he was a boilermaker, single, and he denied specific disease. His affection began about six months previously, when he noticed an enlarged gland in the left axilla which occasioned smarting pains. The glands in the right axilla became next invaded, and later those of the arms and neck, all of which at the date of admission were enormously enlarged, producing œdema of the right arm. A fortnight before this he began to have pain in the chest on deep inspiration.

The patient's condition on admission to the ward was bad. Although his tongue was clean, his bowels were constipated. The veins of the abdomen were slightly enlarged below the umbilicus. Splenic dulness was increased in extent, and there was pain on pressure. Liver dulness extended from the sixth right interspace to the border of the ribs, pressure below this line caused pain.

There was great impairment of the percussion note on the whole of the left thorax anteriorly and posteriorly with ægophony and tubular breathing at both apices. At the right base fremitus was absent, and the percussion note was absolutely flat. Respiration tubular and much prolonged. Change of position changed the area of dulness. The heart was normal.

The skin was very dark and was generally covered with a papular rose-colored eruption which itched intensely, causing him to tear his skin in a reckless manner, and leaving him literally covered with discolored scars and excoriations. The urine did not

[1] Trans. Medico-Chirurg. Society, vol. xviii. p. 68.
[2] Trans. Coll. Physicians of Phila., third series, vol. i. 1874.

contain albumen, was acid, light yellow, having a sp. gr. of 1.022.

The blood was examined on the day after his admission by Dr. Henry, with the following result: Number of red corpuscles per c. cm. 4,440,000, about normal. Proportion of white to red, 1 to 254. The treatment adopted was five minims of Fowler's solution of arsenic twice daily and the external use of tincture of iodine upon the glands.

During the six weeks of his life in the hospital the measurement of his neck increased just below the thyroid cartilage from 15½ in. to 16¼ in., and then subsided to 14½ in.; from the occiput over the chin 18¾ in., increasing to 19¼ and falling to 17½. The axillary glands and, to a less extent, those in either groin increased in size and were the seat of occasional stabbing pains. Œdema, however, progressed, first in the arm, next invading the scrotum and prepuce, right foot and further up the limb to the groin, where the glands about Poupart's ligament had become enlarged. Finally, both legs and the whole right side became œdematous; the dyspnœa, which had always been marked, increased and swallowing became almost impossible. The right pleural cavity filled with fluid. The man gasped for breath, screamed with terror, and cried for a knife that he might end his life. On July 28th he died.

At the autopsy the body was seen to be fairly well nourished. Œdema, from the genital region down, was extreme. The skin was excoriated and covered with a papulo-squamous eruption. The glands of the neck were noticeably enlarged. The thorax contained three or four quarts of fluid and shreds of lymph in the pleural cavities, especially in the left. The left lung was carnified and much compressed. The pericardium was filled with fluid.

The heart was normal, weighing 10¾ oz. There were two small glands at the base about the size of large peas. Above the arch of the aorta was a mass of enlarged and indurated glands, filling the mediastinal space and intimately bound to the trachea, œsophagus, and great vessels. One had undergone cheesy softening.

The liver was of normal color, weighing four pounds five ounces. On section nothing unusual observed. The kidneys weighed 6½ and 7¼ ounces respectively and were intensely injected.

The spleen weighed 12½ ounces, was irregular in shape; not unusually friable. Numerous nodules of a color lighter than the spleen substance studded both surfaces, and varied from the size of a pea to that of a hickory nut. On section larger bodies were found, one being as large as a pigeon's egg. The pancreas was of normal size and appearance.

The mesenteric glands were numerous and very much enlarged. They lay in a mass transversely. A large number of glands situated in front of the vertebral column and on both sides of it seemed to exert a certain amount of pressure on the vena cava. The glands of the groin on both sides were enlarged and indurated, and exerted during life great pressure on the adjacent bloodvessels. On section they were tough, of a gray color tinged with yellow. They were not matted together but of quite distinct form, their size varying from that of an egg to that of a pea. Microscopic examination showed a uniform transformation of the cell elements into a homogeneous glistening material not unlike amyloid.

My colleague, Dr. H. A Kelly, called my attention to a chronic ulcer about the size of a half-dime, situated just within the left nostril at the alar angle. From both nostrils a thin puriform discharge exuded.

As to the nature of this affection, Hodgkin gave his opinion that, structurally, it was a gradual increase of every part of the gland. The latest definition of it is that it is a progressive hyperplasia—an enormous increase in the cellular elements—of the lymph-glands, sometimes also of the spleen with anæmia and the development of secondary lymphatic growths, involving groups of glands in succession in various parts of the body.

It must, however, be distinguished from syphilitic or scrofulous adenitis. In Hodgkin's disease the glands are at first isolated, later becoming agglutinated. The formation of pus is said not to be usually met with, and caseation is extremely rare. Ordinary adenitis pursues a more rapid course at first, and may last for years in a single group, frequently terminating in suppuration without extending to other groups of glands.

Anæmia is common in Hodgkin's disease; the highest blood count which I have seen is in the case which I have recorded, while other cases have shown a reduction of the red globules by one-half or even more. The presence of a nearly normal proportion of the white corpuscles has given this disease also the name of pseudo leucocythæmia.

Retinal hemorrhages are uncommon, while bronzing of the skin, due to the pressure of the glands upon the solar plexus, is not unusual.

But the characteristic feature is the glandular enlargement. Once seen, such a case produces an indelible impression. The neck proper is lost in the huge tumor which extends upon the shoulders disturbing the circulation, perhaps compressing the trachea, possibly even, as in one case, compelling tracheotomy.

The prognosis is bad and the treatment futile. The etiology is involved in great obscurity. Virchow[1] believes that otorrhea usually precedes the cervical enlargement. In view of the ulcer of the mucous membrane of the nose in the case herein reported, it is worth noticing that Mosler inclines to a belief in a local origin of this class of diseases and describes a "stomatite et pharyngite leucemique." Jaccoud,[2] in his description of leucocythæmia, states that often the mouth or pharynx is affected with an ulcerous inflammation having a tendency to hemorrhage. Moreover, he states that the etiology of pseudo-leucocythæmia, Hodgkin's disease, is unknown. Cornil[3] has observed in a case of leucocythæmia an infiltration of the Schneiderian mucous membrane producing a nasal lymphorrhœa. Trousseau gives instances in which chronic irritation of the skin, otorrhea, chronic nasal catarrh, pharyngitis, or irritation of a decayed tooth, gave rise to local glandular swelling which preceded the general development of the disease.

HOSPITAL NOTES.

NOTES FROM THE PARIS HOSPITALS.

(Specially reported for The Medical News.)

REMOVAL OF UTERINE TUMORS PER VAGINAM.

M. Péan gave an interesting clinical lecture a few days ago at the Saint Louis Hospital, on ablation of fibrous tumors or myomata of the uterus, *per vaginam*. He began by stating that it is generally believed that fibrous tumors of the uterus ought not to be removed until they cause great disturbance. This belief is founded on another equally erroneous, which supposes that these tumors are frequently met with and rarely cause much suffering, as they develop slowly, especially in women who have passed the menopause. Those surgeons who see a considerable number of cases do not share these illusions, but can testify that fibrous tumors cause much suffering, render life intolerable, and shorten it more frequently than is commonly supposed.

M. Péan says that after a long experience, after having witnessed the suffering and disturbance these tumors cause, he has come to the conclusion that the surgeon who succeeds in removing them, at the onset, before they become developed, without endangering the life of the patient, renders a greater service to humanity than all the others who perfect methods of operation for removing them when they are fully developed. During some years M. Péan has put in practice these opinions; the results have been most satisfactory. M. Péan does not include small submucous pediculated tumors, only sessile interstitial tumors, forming a projecting, convex mass in the uterine cavity. In such cases, even when the neck of the uterus is just sufficiently dilated to enable the operator to pass his finger, it is impossible to ligate the tumor. There is only one resource, ablation; the tumor must be removed bit by bit. The greatest proportion of fibrous uterine tumors pass unnoticed during the first period; it is not until they cause a bulging above the pelvis that they are recognized. There are a certain number of these tumors which, without being large, cause hemorrhage, compression of the bladder and rectum, and endanger life. The diagnosis is easily made, and surgeons generally seek to arrest the progress of the tumor by medical treatment, but they do not succeed. When the symptoms become serious they remove the tumor by gastrotomy.

M. Péan removes interstitial fibrous tumors *per vaginam*. If the neck of the uterus is not naturally sufficiently dilated he dilates it artificially, or, if necessary, incises it; the surface of the tumor is then seized by forceps made expressly for M. Péan by Mathieu; these forceps take hold of it as close as possible to the muscular coat and crush the vessels which proceed from this coat to the tumor and mucous membrane, which covers it; the portion of tumor thus seized is then enucleated, a second pair of forceps is placed above the first and another portion is enucleated, a third and fourth pair are placed in the same way until the entire morbid mass is removed. When necessary one or two pairs of forceps can be kept in place to assure hæmostasis.

This method has been frequently adopted by M. Péan, but is only applicable when the tumor forms a projecting mass in the uterus. When interstitial tumors are not sufficiently developed to be seized by the forceps, they may nevertheless be removed *per vaginam*. The neck of the uterus should be dissected out and laterally incised on both sides so as to be able to penetrate into the cavity of the uterus; the tumor can then be enucleated without danger of hemorrhage by using the forceps. If the tumor, instead of developing in the uterine cavity is more external, near the vesical and rectovaginal septæ, or even in the peritoneal sac, similar to subserous fibroids, another method should be adopted. The neck of the uterus should be dissected out in its circumference, incised on both sides, the tissues that cover the inner surface of the neck of the uterus should also be dissected, and, if necessary, the peritoneal sac opened. While this operation is going on the parts must be kept out of the way by the retractors, and hemorrhage prevented by the use of pressure-forceps. Care is needed to avoid injury of the rectum, ureters, and bladder. When the inferior surface of the tumor is perceived M. Péan makes a deep incision, then seizes the tumor with dentated forceps; the tumor is then removed bit by bit. Sometimes the mass removed is as large as the head of a nine months' fœtus. Hemorrhage is often abundant, and the important vessels must be then compressed by forceps. The peritoneal incision is left open for some time in order to allow the fluids to escape.

MEDICAL PROGRESS.

Anomaly of the Pupillary Reflex in Dementia Paralytica.—Morselli (*Gaz. degli Ospitali*, Feb. 21, 1886) reported a case before the Royal Academy of Turin of an individual who was an insane paralytic, whose pupil dilated when exposed to the light instead of contracting as usual.

Moss thought that this fact might prove a psychical action.

Reymond said that a trifling brief dilatation of the pupil takes place in the ataxic. Also the first effect of eserine is a slight and rapid dilatation of the pupil.

Morselli observed that his case could not be explained by either of these two interpretations.—*Journal of Nervous and Mental Disease*, May, 1886.

Treatment of Asthma by Cauterization of the Nasal Mucous Membrane.—At the session of the Berlin Society of Internal Medicine, held May 17, 1886, Dr. Zublinski presented a memoir on the subject above stated. The results obtained in his personal practice may be thus summarized:

He had encountered 143 cases of asthma complicated by diseases of the upper air-passages, in which operative treatment directed to the latter disorders was frequently productive of good results in the chief disease. The cases are classified as follows:

Asthma associated with hyperplastic rhinitis, 55 cases; 8 cured, 3 improved.

21 cases with granular proliferation of the inferior turbinated bone; 6 cured, 4 improved.

11 with similar lesions of the middle turbinate; 5 cured, 2 improved.

9 with disease of the septum and 5 with tonsillar hypertrophy; 2 cured, 1 improved.

28 with various lesions of the pharynx; 3 cured, 1 improved.—*Journ. des Sociétés Scientifiques*, May 26, 1886.

CONSTIPATION IN INFANTS is thus discussed by various contributors to recent numbers of the *British Medical Journal:*

Dr. W. R. Cossham has generally found much benefit from ordering the infant to be fed every morning with a cupful of gruel, which may be sweetened with treacle or honey. Further help is obtained by giving a teaspoonful of cod-liver oil twice a day, and using friction over the bowels every night with olive oil on the palm of the hand. An occasional morning draught may also be necessary, such as tinct. podoph. ♏iij (gr. ij ad ℥j); pulv. ipec. gr. ¼; glycerini ℥j; aquam anisi ad ℥ss.

L. suggests two or three meals of "Mellin's food," daily. He has found this useful, and has long since dispensed with drugs as much as possible in the treatment of some troublesome cases. If the infant is being nursed, two or three meals a day will be sufficient, and these may be dispensed with as soon as the object is attained, and resumed if necessary; but if it be living upon artificial food, "Mellin's food" should be substituted.

Mr. E. Gibson Berkley says that the liquid extract of cascara sagrada, combined with minute doses of tincture of nux vomica, and made palatable with a little syrup of lemon or glycerine, will be found very useful. It should be given two or three times a day.

Sign-Post recommends feeding the infants on well-made oatmeal gruel and milk, in proper quantities, and at intervals. For an infant from four to six months old, he advises half the feeding-bottleful of milk, with the same quantity of oatmeal gruel, to be given every four hours. The directions for preparing the gruel are as follows: Take a teaspoonful of the common coarse, but sweet (not bitter), oatmeal; let this soak in a little more than a tumblerful and a half of cold water for some hours, say all night; then place this meal, and the water, in a clean, covered saucepan capable of holding double the quantity of the liquid poured in; place the saucepan near the fire, so as to heat the contents slowly, and after a time place it on the fire, and stir the contents, until, and for a minute or so after, it boils; then pour the contents on to a horsehair sieve; the creamy gruel is made.

Mr. M. F. Bush advises a spill of paper dipped in castor-oil about two or three inches, and inserted into the lower bowel. It should be used every day for a time.

LARGE DOSES OF DIGITALIS IN PNEUMONIA.—In a Roumanian medical journal, *Spitalul*, February, 1886, DR. I. ANTONIU, of the Military Central Hospital in Bucharest, describes an interesting case of a weak soldier, aged twenty-three, who was admitted to Prof. Z. Petrescu's wards about twenty-four hours after an initial severe rigor, with grave (*forte alarmâtóre*) general and local symptoms of pneumonia. At once an infusion of digitalis (four grammes of the leaves to two hundred grammes of water, the whole to be taken in frequent doses during the day) was given. The same treatment was pursued during the next day (the third of the disease). On the morning of the fourth day the temperature suddenly fell from 39.5° C. to 36.3° C., and the pulse from 92 to 60 a minute. On the fifth, the temperature was oscillating between 36.3° and 37°, a marked amelioration in the local symptoms being observed. On the sixth, the patient's general state was quite satisfactory. On the tenth, he was practically well, but was retained under observation for other eight days. For several days the pulse continued to be as slow as 44 to 48 a minute, it being still 52 twelve days after the last (second) dose of the drug.—*London Medical Record*, May 15, 1886.

PAINLESS EXTRACTION OF TEETH WITH THE AID OF COCAINE.—BIGNON records several cases in which teeth were extracted without pain by the subgingival injection of a twenty per cent. solution of cocaine benzoate. The method as at present practised, seems somewhat complicated, but is probably capable of simplification. A preliminary injection of two or three drops of the solution named is made in the internal portion of the gum of the carious tooth. After waiting forty seconds to one minute, a second injection of the same amount is made at the same point, but somewhat deeper. After a second delay of one minute the tooth is removed. The second injection is not felt. It is interesting to note that no unpleasant results have been observed from this method, although the equivalent of three-quarters of a grain of the alkaloid was used.—*Les Nouveaux Remèdes*, May 1, 1886.

REFLEX NASAL COUGH.—In a paper thus entitled, MR. E. C. BABER presents, in *The Practitioner* for July, 1886, the following conclusions based upon the clinical study of six cases:

1. Reflex nasal cough is only exceptionally produced by probing the anterior part of the inferior and middle turbinated bodies and the tubercle of the septum.

2. In children it is not very uncommon to find that a slight hacking cough can be produced by irritating the anterior end of the inferior turbinated body.

3. The cough reaction may occur without erection of the inferior turbinated bodies, and may be intermittent in character.

4. Reflex nasal cough and the act of sneezing are very closely associated, and probably represent different forms or degrees of the same irritation.

The practical outcome of these considerations is, that in cases of spasmodic cough not otherwise to be accounted for, we should do well to examine carefully the nasal cavities in regard to the reflex irritability of their lining membrane.

SPARTEINE AT HOME.—DR. THOMAS H. BUCKLER writes as follows to the *Boston Medical and Surgical Journal* of June 30, 1886:

"The expensive sparteine lately recommended by Germain Sée for cardiac weakness, is prepared from Scotch broom—spartium scoparium—the *Planta Genista* or emblem of the Plantaganets, which grows in many parts of the thirteen original States, on sterile soil. It was brought over here by the Scotch and English to prevent the washing of gravelly roads and gutters. It should be cut and gathered at this season, and dried like hay. Its active principle is extremely soluble in water, and two ounces of ground or contused stems to a quart of boiling water, a wineglassful for a dose, every eight hours, are equivalent to a grain and a half of the prepared gum used by Dr. Sée. This remedy is useful not only in failure of the cardiac ganglia, but as a tonic to the organic and vasomotor nerves in whatever part

of the body congestions occur from loss of power in them. I have used this agent in the form of infusion for half a century, and with marked advantages in many cases."

Sudden Death from Corpulency.— Professor Kisch, of Prague and Marienbad, has recently collected statistics, and written a contribution in the *Berliner klinische Wochenschrift*, on the frequency of sudden death amongst extremely stout persons. In nineteen cases of this occurrence, acute congestion of the lungs was discovered in twelve cases, cerebral hemorrhage in six, and rupture of the heart in one. The pulmonary congestion arises, as Dr. Welch has already shown, from paralysis of the muscular walls of the left ventricle, while the right side of the heart continues to act with almost normal vigor. The apoplectic symptoms were traced, in most of the cases, to arterial sclerosis, a very frequent concomitant of extreme corpulency. Rupture of the heart is due to the overworking of the walls of the left ventricle, which, being involved in fatty infiltration and degeneration, can no longer increase in size, in proportion to the extra work which it has to perform. The failure of heart-power appears always to be the immediate cause of death, which generally follows immediately after violent exertion, or an excess in drink or diet. Stout subjects over fifty years of age are very liable to fatal syncope, which, however, is frequent amongst the corpulent at earlier periods of their lives.—*British Medical Journal*, May 15, 1886.

Aneurism of the Subclavian Artery Cured by Galvanopuncture.—Dr. Saboia has presented to the Imperial Academy of Medicine of Brazil, the history of a case of aneurism of the right subclavian artery in a man aged thirty, cured by galvanopuncture. The tumor was of the size of a small hen's egg, bounded on the inner side by the sterno-mastoid, below by the clavicle, and on the outside by the trapezius. There were no difference between the pulsations of the two carotids, but the radial pulse of the left side was strong, full, and vibrating, while on the right side it was small, filiform, and scarcely perceptible. Two metallic needles were introduced into the tumor, and connected with the positive pole of a Gaiffe's pile of fourteen elements, the negative pole being applied to the trunk at a distance from the aneurism. The sitting lasted thirty-five minutes, at the end of which the tumor had become tense and had ceased to pulsate.—*London Medical Record*, May 15, 1886.

Inoculation for Anthrax in India.—Recent experiments on the inoculation of stock for anthrax, in Madras, have attracted the attention of the Punjab Government, which is considering a circular on the subject. The Inspector of Cattle Diseases for Madras submits a lengthy report, which deals more with Dr. Klein's observations on Pasteur's anthrax vaccine than the work in hand. This much, however, can be gathered from Mr. Mills's statement. One hundred and nine government animals, and nineteen head of cattle belonging to ryots have been inoculated with vaccine from Paris during the past two years; and the result of these inoculations has been perfectly satisfactory. During the preliminary experiments to test the strength of the vaccine after its voyage out, everything went well as long as the doses laid down by Pasteur were adhered to. An unlucky guinea-pig, however—guinea-pigs and rabbits supply the rank and file of the noble army of martyrs to science—was over-inoculated, and died with all symptoms of well-developed anthrax; proving by its death that even the attenuated vaccine used in the first inoculations is not to be trifled with. Mr. Mills holds that, in view of the frequency and destructiveness of anthrax outbreaks in India, and the hopelessness of dealing with the disease when it has established itself anywhere, protective inoculation of stock should, if at all possible, be insisted upon. That is to say, a staff of veterinary assistants should do for cattle what the vaccinator in the district does for man. Setting aside the difficulty—no light one, as the report will show—of keeping up a constant supply of trustworthy vaccine in India, we are brought face to face with the reluctance of the ryots to accept any new thing; and the blind suspicion with which they would naturally regard any man syringing an unknown horror under the skins of their kine. Mr. Mills has had the results of Pasteur's labors translated and distributed to cattle owners; but the result is not inspiriting so far.—*The Indian Medical Gazette*, May, 1886.

Effect of Mental Overwork upon the Teeth.—Among the hard-worked pupils of the Paris public schools, the teeth become deteriorated in a few weeks after entry. The second dentition is often premature. These observations confirm the statements of Dr. J. L. Williams, who has given great attention to this subject. He has shown that any mental strain shows itself upon the teeth in a short time, both in increased decay, as well as in increased sensibility of the dentine. Dr. D. M. Parker has reported that these same changes are always apparent in men who are training for athletic trials. As there is not the slightest doubt of the accuracy of these observations, they show that these are matters which demand serious consideration from educators.—*Boston Medical and Surgical Journal*, June 3, 1886.

Toxic Effects of Corrosive Sublimate used as an Antiseptic.—This substance has come into very general use during the last few years, in the form of a solution, as an antiseptic. There can be no doubt that it possesses very considerable antiseptic powers; but, unfortunately, it is also a violent poison, and abundance of cases are now on record which show that its use is often attended with very great risk of toxic effects resulting from its absorption. In a paper recently contributed by Dr. Lucien Butte to the *Nouvelles Archives d'Obstétrique et de Gynécologie*, a long series of such cases are adduced, in many of which a fatal result followed persistent vaginal injections of the solution of Van Swieten (1 in 1000). The symptoms of poisoning were the more difficult to detect from the fact that, occurring during the puerperal period, they were masked, to some extent, by those incidental to this state. They consist principally of hypogastric pain and tenderness, violent abdominal pain of a colicky character, accompanied by frequent mucous stools, often stained with blood. The urine is generally diminished in quantity, and contains epithelial cells, casts, and more or less albumen. Salivation is most frequently

absent, but the mouth and throat are red and dry, and there is marked thirst. Dr. Butte is inclined to consider that absorption occurs most frequently in cases where lacerations of the perineum, or of the cervix uteri, have taken place, or where large ulcerating surfaces are present. The toxic effects are naturally more marked in debilitated and cachectic patients. The post-mortem appearances are indicative of enteritis, with sloughing of the mucous membrane of the large intestine, while the kidneys are enlarged and anæmic. Deposits of crystals of oxalate of lime are common in the uriniferous tubules, due, it is suggested, to the decalcification of the bones, which is said to result from the presence of the bichloride in the system. As Dr. Butte quotes no fewer than twenty cases, in which the fatal result was attributed to absorption of the mercury, it is evident that, in obstetric practice at any rate, the use of even extremely dilute solutions requires very great caution.—*British Medical Journal*, June 19, 1886.

Circular Cauterization in Opacity of the Cornea.—M. Louis Vacher, of Orleans, finds that in cases of corneal sclerosis or episcleritis better results can be obtained by circular cauterization lightly performed with a loop of wire heated by the galvanic current, than by the more usual method of passing a knife round the edge of the cornea. In one case, after eighteen months of this treatment, a patient who had been unable to see from corneal opacity for fourteen years, recovered the power of vision. In another, a cornea which had been absolutely covered with leucoma for ten years, had in two years become sufficiently transparent for the performance of iridectomy. M. Prouff confirmed M. Vacher's statement, stating that he himself had three times operated in this manner with the most complete success.—*Lancet*, July 3, 1886.

Successful Gastrostomy.—A case of gastrostomy under the care of William Square, F.R.C.S., is thus recorded in *The British Medical Journal* of July 3, 1886. J. W., aged sixty-two, a monthly nurse, was admitted on April 10, 1885. For some months she had had progressive difficulty in swallowing. About a week before admission she came to an absolute stop. Her history was good. Some blood in the vomit, and increasing tenderness, prevented the passage of any tube. Without operative interference, it was evident that she must die very soon.

On May 1, 1885, the first part of the operation of gastrostomy was performed after the usual custom. The stomach was easily found, and silver sutures were used. Nutrient enemata consisting of beef-tea and brandy, with some tincture of opium, were given every four hours.

On May 3d the stomach was opened with a Gräfe's cataract-knife. A soft India-rubber tube was introduced, being retained in place by a suture passed through it; one ounce of peptonized milk was given every two hours by the tube; in addition, one enema was given every five hours.

On May 9th peptonized strong beef-tea (two ounces) was given every three hours by the tube. The temperature was always normal, and there were no symptoms after operation but slight retching for two days. She was discharged on May 23, 1885.

On April 6, 1886, she looked almost as well as ever. She had travelled to Brighton and back, and, by the courtesy of the guard, fed herself *en route* in a separate compartment. She always laid down to feed. There had been an interval of one month during which she could swallow as well as ever, even hard meat and crusts. During all this month, however, she vomited mucus and blood until the capability of swallowing ceased.

She was in the habit of making her day's food each morning—a large basinful of beef-tea, bread, and milk. She injected as much as she wanted when hungry. Her meal-times corresponded with those of the family. Her mouth watered before. The only thing that she could taste when injected was whiskey. It had the usual alcoholic effects. She appeared very well, and it seemed that the diagnosis of carcinoma might be wrong.

On April 14, 1886, she was taken suddenly ill with vomiting, and a condition of semi-collapse. A large amount of green, highly offensive, pus was discharged by the side of the tube. She slightly recovered, but, up to the time of her death, took in but little, and was constantly sick. The green pus was always exuding, more or less, by the side of the tube. She became gradually worse, and sank on April 25, 1886.

At the necropsy the whole of the lower part of the œsophagus was one enormous ulcer; but there was no thickening or suspicion of cancer. The whole mucous membrane was simply destroyed. It was very offensive. The mucous membrane of the stomach was not healthy, but had nothing very remarkable about it. The orifice of the hole was very peculiar. I had expected to see it valvular, or dilated into a funnel; but it was no larger inside than out, being perfectly circular, and about the size of a No. 16 catheter. There was a little left pleurisy, but nothing else to record. I think we may say that the poor woman had one year of happy life, without ache or pain; and hence I am justified in calling this a case of "successful gastrostomy."

The Uses of Eserine Sulphate in Diseases of the Eye.—In a paper read before the Philadelphia County Medical Society, on June 16, 1886, Dr. H. F. Hansell presented the following conclusions:

From the reports of others, and from my own experience, I feel justified in concluding that eserine is indicated: 1. In acute affections of the cornea, involving the deeper layers. 2. In threatened perforation. 3. In diseases of the cornea where atropia fails to cure, and where the danger from posterior synechia and subsequent iridectomy is less than the present danger to the cornea. 4. In prolapse of the iris and beginning staphyloma. 5. In some cases of dislocated lens. 6. In paralysis of the ciliary and iris branches of the third nerve. 7. In glaucoma.

De Wecker sums up his opinion of eserine in these words: "In the use of eserine a step in advance has been made in ocular therapeutics. I do not exaggerate when I say that, thanks to our being able to substitute it for atropia, we are able to save eyes which formerly would have recovered, if at all, with more or less considerable staphyloma—a condition which would have left scarcely any hope of a restoration of vision. Furthermore, the powerful aid rendered by eserine should encourage any careful practitioner not to resort too readily to surgical interference in abscess of the cornea."—*College and Clinical Record*, July, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 17, 1886.

PHYSICAL TRAINING IN AMERICAN COLLEGES.

IT is a startling fact announced by Dr. Sargent, of Harvard College—than whom no one has better means of knowing the truth—that "half the young men who come to college are physically in arrears." If that be so when they first go to college, and no provision be made for them to gain in bodily vigor while in college, what must be the result? What is the result? We see it all around us. Scholarly men in broken bodies, a large part of their mental capacity undeveloped for want of a better physical basis; snarling dyspeptics ever complaining of their stomachs, like Carlyle with his castor-oil,—"that oil of sorrow;" early graves quenching many a large and brilliant future that "might have been."

But a new era has dawned within the last twenty-five years. Mr. Higginson, writing of gymnastics in 1861, well said that the educational systems then in vogue always contemplated man as a sedentary animal, and that it was something to have outgrown the period when active sports were prohibited. In his early days there was but one boat in Cambridge, and the faculty suppressed that under a college law prohibiting a student from keeping any "domestic animal." In these twenty-five years there have been built thirty-three distinct gymnasiums in educational institutions, the total cost of which has been over $600,000. Amherst College led the way, not only in first providing a really good gymnasium in 1860, but in grasping the real idea of what such a department meant; and Harvard, following in 1879 with her magnificent Hemenway gymnasium, has still further developed the idea. In fact, these fine gymnasiums only gave the chance for Dr. Hitchcock and Dr. Sargent, two men of force and large ideas, to impress themselves on the community.

Most people—even educated men, and doctors among them—unless familiar with the "Sargent System," have an idea that a gymnasium is a place which anyone may go to perform feats of muscular strength, and so to become an acrobat or an athlete, and if he cannot do this there is no use of his going there. That is the fundamental idea of "College Athletics," as seen in stated contests by athletic associations, in rowing, baseball, and football matches.

But "Physical Training" in American colleges, in the proper sense—in the sense of Hitchcock and Sargent—is a very different thing. In college athletics only the athlete can excel, and in many games the strength and science are such that only the few who are strong and skilled can take any part whatever. But the "physical training" of to-day contemplates the whole body of the students, that every one shall get his share of good out of it. The weakly are more cared for than the strong. Every man is measured and gauged in all parts of his body, and those who are deficient are "prescribed for" intelligently, as an oculist does for myopia or a physician for a pneumonia. It is directed not only to muscular development, but to the state of the skin, the digestive organs, the heart, the lungs. It looks less after how many pounds one can lift than after his diet and drink, his hygienic surroundings, hours of study, general bodily vigor, habits and tastes, and adds to these the needed exercises. "Developing apparatus" plays a large part in the scheme. The weak parts are sought out and built up by them so that a symmetrical whole shall result in which no overdevelopment of one part shall take place, the body shall not be weak while the brain is strong, the legs shall not be unduly strong, and the arms or back weak. And all of this is contemplated as a part of the college curriculum, in which the Professor of Physical Culture shall be a physician and a member of the faculty, and the physical development is as much a college duty as mathematics or Latin, or any other study—truly a new idea in a college course!

Of course, many men will go further and develop more or less into athletes, but the object of college gymnasiums and college physical training, it cannot be too strongly stated, is not this, but it is to develop the physical health—and, as a consequence, the mental vigor—of the whole body of the student, and especially of the weaker ones who need it most.

We have been led to these remarks by reading Circular No. 5, of 1885, of the Bureau of Education on "Physical Training in American Colleges," by DR. E. M. HARTWELL, of Johns Hopkins University. This elaborate paper is alike creditable to the author, the University in which he is the able Instructor in Physical Culture, and to the wise management of the

Bureau of Education. In it will be found views and ground-plans of most of the good college gymnasiums, with lists of their apparatus, where this can be had, the architects of the buildings, the various physical examinations to be made, and, in a word, all the information one could desire on the subject. Dr. Hartwell has dealt with the subject with his usual thoroughness, and has made all colleges his debtor for the information, and especially for the intelligent way in which he describes and enforces the new education in its care of our bodies. Amherst and Hitchcock founded the new system, Harvard and Sargent have developed it, and the Bureau of Education and Hartwell will popularize it.

MASTOID OSTEITIS.

THE occurrence of suppuration within the mastoid cells is usually associated with disease of the middle ear, and in a certain number of cases it is limited to the sinuses. In others it begins in them, and afterward attacks the substance of the bone itself, producing a secondary osteitis. In a third class of cases it is primarily a bone disease, and, perhaps, this occurs oftener than is generally supposed. In such cases there may be present any of the ordinary forms of inflammation of bone, or of its periosteum, or of both. And the fact that the inflammation may occupy a variety of situations is of the utmost consequence. It may be in that part of the bone which is most accessible, and which is usually approached with the expectation of finding pus when the symptoms point to its formation, or the inflammation may be confined to the parts of the bone which form the inner aspect of the mastoid process, and which are difficult of access. This fact may account for the fruitless incisions which have at times been made by excellent surgeons, and for an unfortunate prolongation of the sufferings of a patient, or even a fatal issue of a case which might have terminated happily if the process of mastoid osteitis had been better understood.

The nature and treatment of "some of the less common forms of mastoid disease" have been studied recently by J. ORNE GREEN, who, in a paper bearing this title, in the *Boston Medical and Surgical Journal*, April 15, 1886, reports the histories of two cases in which it was necessary to extend the customary incision over the mastoid process behind the ear, to a point below its tip, and to penetrate below the sterno-mastoid muscle in order to give exit to pus. In addition to the interest which attaches to the method adopted in these cases, they have a special interest as bearing upon the points to which we have called attention above. It is usual to speak of suppurative inflammation of the mastoid bone as an extension of a process of suppuration in the middle ear. But, as we have already said, it may undoubtedly be a primary affection of the bone itself. Analogy, the symptoms of many cases, and the history, which often discloses no recent attack of osteitis, and not unfrequently indicates the occurrence of an acute infective disease, all point to the plausibility of referring these inflammations to the bone itself, or to its periosteum. In one of Green's cases the patient had an abscess of one of the ribs when he came into the hospital, and subsequently developed an inflammation of the tympanum and mastoid process. Here we have a history which corresponds to that of many cases of infective osteomyelitis, and we think it worth while to call attention to this view of such cases, because it has an important practical bearing upon the treatment of certain forms of inflammation of the mastoid process which are probably not very rare.

A PLEA FOR A CHEST HOSPITAL.

ANY one who has watched the condition of the victims of pulmonary consumption among the poor, must feel that their lot is in many respects more pitiable than that of any other class of patients—the insane not excepted. Hopeless as their case very often is, it becomes doubly so on account of the meagre medical benefits which can be rendered them. General hospitals seldom receive them, and to the poorhouse they generally refuse to go, and if they find no charitable friends they end their lives in a miserable hovel, or perhaps in the garret of a tenement house.

General hospitals have as much justification in refusing to admit them as the unfortunates have in declining to enter the poorhouse, for neither is adapted to their proper care and treatment. Lung affections are a special class of diseases, and they require as much special treatment as diseases of the eye or of the skin, or diseases of any other class. To the people of this country the idea of special hospitals for chest diseases is a comparatively new one. But it is not so in Europe, where many of the most important cities contain large institutions exclusively devoted to their treatment.

No other class of diseases has received more scientific attention from physicians, particularly during the last decade, than those of the respiratory organs, and it must be sadly confessed that the gain has been entirely incommensurate with the amount of work expended. Cod-liver oil, the hypophosphites, malt extracts, koumiss, forced feeding, compressed and rarefied air, inhalation of oxygen, and of nitrogen, antisepsis, cold and hot baths, cold douches, external applications, and a host of other remedies and expedients have been launched before the patient, yet the disease continues in its fitful and triumphal course. The recent discovery of the bacillus tuberculosis inspired the hope that this microörganism maintained a causative relation to the disease, and that

the true and rational treatment of consumption consisted in efforts to extirpate this parasite. This plan has, also, been tested from every conceivable approach, and thus far has yielded no decided beneficial results.

There can be no question that very many of the methods which have been advocated and recommended are capable of yielding excellent results, but the most salient reason for their failure to accomplish what they should lies in the fact that we have no buildings suitable to combine these methods for the greatest possible good to the patient—a building in which he is under the constant and entire control of either nurse or assistant, and in which he is enabled to pursue a systematic course in regard to everything pertaining to his welfare. Such a building should be erected in a healthful locality, possess the best heating and ventilating apparatus, good drainage, a pure water supply, ample conveniences for outside and indoor exercise, glass pavilions for exposure to sunlight during winter, hot and cold baths, douches, appliances for the inhalation of compressed and rarefied air, etc. In such an institution the patient would be under immediate observation, and could be directed what to do in relation to eating, drinking, sleeping, exercising, amusements, and the application and administration of remedies for the whole twenty-four hours of every day.

Serious objections are very often presented against a collection of many consumptives in one building or locality, inasmuch as it is urged that it increases the danger of infection and contagion. There is good ground for believing, however, that the risk from this source is more imaginary than real, a view which is strongly supported by the statistics of the Brompton Hospital for Consumption in London, and similar hospitals elsewhere. That phthisis is infectious or communicable from man to man, few will deny, but that it is so contagious that those affected with it require constant isolation is a statement not warranted by facts, and is too bold and too cruel an assumption to merit serious consideration. It is urged, moreover, that those who are in a more or less hopeless state exercise a depressing and discouraging influence on others who are in the incipiency of the disease. The testimony, however, of those who have spent many years in institutions of this kind shows that this timidity disappears in a very few days after admission, and that this influence is felt most by those who are the most desperately ill. A commingling of these patients, on the contrary, it is found creates a sympathy for each other's sufferings, and force of example, which their association engenders, is most useful in stimulating them to do things in the way of treatment which they could not otherwise be induced to undertake.

Unchecked and undaunted as consumption presents itself to-day, it is evident that home treatment, as compared with hospital treatment, is a failure, and that more decided measures must be instituted to cope successfully with this disease. Recent statistics show that the highest percentage of favorable results in chest diseases is derived from special hospital treatment, singly and alone. We trust that some of our wealthy philanthropists may have their benefactions directed to a channel in which their liberality may be applied in the relief of the suffering of this hitherto neglected but most deserving class of patients.

THE USE OF MEDICINES TO CAUSE ABORTION.

AT a recent meeting of the Gynecological Society at Hamburg, the proceedings of which are recorded in the *Centralblatt für Gynäkologie*, May 22d, LOMER reported the case of a woman who, when four months pregnant, took stramonium for the purpose of causing abortion; grave symptoms of poisoning followed, but she recovered, and the pregnancy was unaffected. She was advised by another woman to take the medicine for the purpose indicated, so that there seems to be a popular belief that stramonium is an abortifacient. Lomer, however, could find in none of the reported cases of stramonium poisoning an instance in which this agent caused miscarriage. He next turned his investigations to the question as to whether belladonna, belonging to the same family and having analogous effects, is an abortifacient; but he also failed to find any published case of belladonna poisoning in which miscarriage occurred. He was led to make this inquiry as to belladonna from the fact that Ploss states that the Greeks use this agent for the purpose of causing miscarriage. It is true that Ploss in that wonderful collection of information pertaining to woman in all ages and among all peoples, *Das Weib*, does state that the Greeks use belladonna for the purpose mentioned, but he does not state that it is administered internally; it, in combination with opium, is introduced into the vagina, and then other means are used in addition.

Lomer's conclusion was that no medicines are certain to act upon the impregnated uterus, with the result of terminating the pregnancy. In the discussion which followed, RATJEN thought that aloes had some effect, which was denied by Lomer. HÄCKERMANN had seen abortion follow the use of cognac; and, on the other hand, PIZA saw a pregnant woman who drank three-fourths of a litre of "Rosmarinschnaps," and she did not miscarry. PROCHOWNICK had seen active laxatives result in miscarriage, and HAPPE had seen an instance in which a pine-tree cone inserted in the vagina failed to cause miscarriage. RÆTHER stated that in the rural districts of West Prussia, savine, oil of amber and arsenic were

used as abortifacients; but such specific action was only observed when they produced a severe gastro-enteritis.

For our own part, we have met with two instances in which pregnant women took a preparation of May-apple in such large doses, for the purpose of causing miscarriage, that they were brought to a condition of great prostration by violent purging and vomiting, and in neither instance was the pregnancy interrupted. The general conclusion of the profession as to the action of reputed abortifacients is that such medicines do not exist. An emetic, or a drastic purgative may, in a given case, be followed by abortion, but the same means might be used in fifty other cases of pregnancy without such a result following.

SOCIETY PROCEEDINGS.

NEW YORK COUNTY MEDICAL ASSOCIATION.

Stated Meeting June 21, 1886.

The President, C. A. Leale, M.D., in the Chair.

Dr. Edward G. Janeway read a paper on

THE DIAGNOSIS OF CERTAIN OF THE INFECTIOUS DISEASES.

For a number of years, while occupying the position of Health Commissioner, he said he was so placed that it was necessary to give a great deal of attention to this matter. He was also thus enabled to see those circumstances which are most liable to lead to mistakes, and at times to witness the sad effect of some of them.

The diagnosis of smallpox when it presents itself with all its ordinary characteristics is a matter of no special difficulty to one who has previously seen a few cases. But owing to the system of persuasive vaccination carried on in New York, and presumably to somewhat the same extent in other cities of the country, for the past nine or ten years, there had been comparatively little of the disease. Systematic vaccination in general, vaccination in the neighborhood where a case of smallpox had occurred, isolation or removal of the patient, disinfection of premises, and subsequent careful outlook for other cases in the neighborhood, had been successful to an extent appreciated by few. But Dr. Janeway thinks that the outlook for the future is not so assuring, as the work of vaccination has been crippled to a considerable extent during the past year, and a large contingent of infected persons exists, who may become victims to and spreaders of smallpox.

He has known the start of a considerable outbreak of the disease to be traced to a single erroneous opinion. Another very unfortuntate circumstance had happened which would tend to delay the prompt action desirable in dealing with the disease. The law had been invoked to inflict a penalty upon a physician who had reported a case of suspected smallpox to the Board of Health, and though an appeal had been taken which would probably be successful, yet the effect was unfortunate. It seemed to him that the case of the physician dealing with disease, and particularly with one which is dangerous to the public health, ought to be protected by law.

One of the greatest safeguards against an error of diagnosis as regards smallpox, consists in having such a classification of the disease fixed in the mind as should serve to take account of the various methods of its manifestation. In a number of the text-books important facts bearing upon the method of development of certain forms of smallpox are omitted. A satisfactory classification he had found as follows:

Purpura variolosa.	
Variola verâ . . .	Confluent. Semiconfluent. Discrete. Corymbosa. Hemorrhagic.
Varioloid	Variola varicelloides.

The distinction between purpura variolosa and the ordinary hemorrhagic type, where the blood is extravasated into the vesicles, should be kept in mind, and it can be best accomplished by making such a classification as the one referred to. In his experience, the failure to recognize, or even to have any knowledge of the existence of this form of the disease, has led to very serious consequences. The danger consists in mistakes between this form of the disease and the malignant type of some of the other infectious diseases, particularly measles, and, much more rarely, typhus fever, ulcerative endocarditis, and purpura hemorrhagica.

A careful cross-examination of the patient and his friends should be made, and, at the same time, the possibility taken into consideration that a visit to a strange place, the getting of new clothing, etc., might, in the absence of any other clew, furnish one. In these days of rapid travel, with emigration to the West, in that section of the country, as well as here, the recent arrival of strangers in the neighborhood must be thought of. Should it be learned that a possible exposure had happened, and to a case of disease of unknown nature, it should be a part of our duty to ascertain by inspection of such sick person, or by inquiry of the physician in attendance, the nature of the illness.

By way of illustration, Dr. Janeway related the following case: Some years ago he was called in consultation to another city to decide as to the nature of a strange variety of fever. One patient had died of it, and another was seriously ill at the time. When seen, the latter was sitting in bed, with very feeble pulse, though with only slight febrile movement, and showing evidences of dyspnœa, due to changes in the blood. He had a wet cloth on the forehead which concealed a number of purpuric spots in the skin of that part; while on the chest, abdomen, and legs these purpuric spots also existed. In one place there was a small vesicle (which was, however, of no determinate character), and at no point were there any papules or umbilicated vesicles. His mind was perfectly clear, and this was the sixth day of his illness. The hemorrhages had only appeared in the skin of the forehead on the morning of that day; but the eruption on the rest of the body had already existed for more than a day. Dr. Janeway suggested that the disease was in all probability purpura variolosa; in which opinion he received

confirmation, *first*, by hearing that this patient had attended the one who died, and had held her in his arms, the fatal issue having taken place about twelve days before the beginning of his own sickness; and, *second*, by asking about the others who had been exposed during the sickness and at the funeral of the first patient. He learned that a number of these individuals were down with fever and that one had an eruption. The latter proved to be discrete smallpox. The two cases with hemorrhagic extravasation were, then, undoubtedly variola, but of a form which none of the attending physicians had previously encountered. Quite an outbreak of variola occurred in that city.

This case illustrated better than any words these three points to be considered in establishing a diagnosis:

1. It is important to know the nature of the disease from which a malignant case, not itself possessing positive features, has developed.

2. Should the patient have died, this may be done by an investigation of others exposed to the originating case; these having perhaps a milder and more characteristic type of the malady.

3. The result of the exposure to the malignant case may in some instances be a proof of the nature of the disease.

In other words, we must take into consideration what gave rise to the disease in question, and what has been produced by it. Even in a large city, and in the case of homeless tramps, a rigid inquiry and cross-examination would do much toward throwing light on these cases. What he wished to emphasize was, that we must not be content to consider simply the eruption and patient's condition; but must use every means in our power to establish a correct opinion as to the nature of the disease producing this state, which is denominated purpuric or malignant. It is a great mistake to suppose that hemorrhages from mucous surfaces, a previous diffused scarlatinal-like rash, or maculo-papules becoming flattened purpuric spots, are necessary accompaniments of this type of hemorrhagic variola. Variations from this form which he had described were met with, up to that in which characteristic spots of smallpox eruption occurred.

Dr. Janeway here introduced another case to illustrate the necessity at times of making an autopsy to decide the nature of the doubtful disease. It was one in which an atypical case of smallpox was mistaken by the attending physician for cererbo-spinal meningitis; and two weeks after the death of the patient a gentleman who had been with her during her illness and had refused vaccination subsequently because he felt confident that the disease was not variola, sickened with, and died of, confluent smallpox.

The mistake in differentiating between scarlatina and smallpox occurs in those cases of variola in which a marked red efflorescence first occurs, and in which shortly darker spots and papules, followed by vesicles, appear. In some cases petechiæ occur in places and hemorrhages follow; and not seldom, in severe cases, he has seen the vesicles first on the inner sides of the thighs, and in the axillary space, the face being free. As the throat may be sore at this time, a mistake may occur and the order of events not kept in mind, which is two or three days' sickness, and then the rash and sore throat and mouth, due to the eruption. A mistake which he had known to occur was to consider the vesicles in such a case as sudamina. One point is to be borne in mind, viz.: that an examination which leaves out an inspection of the abdomen and chest, and particularly of the inguinal and axillary regions, will be very apt to lead to a mistaken opinion in the case of a severe infectious disease.

Again, the mistaken diagnosis of measles occurs in a twofold manner. On the one hand, the first stages of smallpox eruption prior to the formation of the vesicle, lead one who looks hurriedly at a case, and does not consider the previous invasion symptoms, to speak of measles. The other mistake occurs to one who looks at a severe case having the skin red, and in it a number of dark maculo-papules, together with hemorrhages of larger extent, and having hemorrhages from other places, as the nose, etc. One who has seen the first stages may have considered it as already shown to be scarlet fever, whereas, a little later, the numerous papules will lead to the mistake of black measles.

The mistake between syphilitic eruptions and smallpox is generally to consider syphilis as variola rather than the reverse. Most of the mistakes are dependent upon want of close observation of the whole eruption and of a consideration of the history of the case. The multiformity of the rash, the condition of the glands, and the duration of the disease will determine, in a large number of cases, the correct diagnosis, to which the history will add confirmatory evidence. Two illustrative cases were given by Dr. Janeway. One additional point had been observed, viz., absence of the eruption on the hands and feet and in the mouth in cases of a syphilitic pustular eruption otherwise pretty generally distributed over the body. In his experience syphilis causes more mistakes in diagnosis than any other disease or eruption, excepting only measles.

Mistakes between variola and varicella are not infrequently made. The distinction of typical cases is sufficiently easy, though he thought students are not infrequently puzzled by finding opposing statements regarding the appearance of the varicellous eruption, not only in different text-books, but also, at times, in different parts of the same work. The danger in mistaking varicella for varioloid is in paying too close attention to the eruption, for sometimes a slight induration is met with at the base of some of the spots of varicella, due to irritation. A careful scrutiny will generally show on the back and buttocks, and behind the ears, characteristic spots, whilst in other places the eruptions may be more or less altered. In cases of doubt between variola and varicella, attention should be paid to the cause of the attacks if known, and to the time of the development of the eruption after the commencement of sickness. Dr. Janeway has known of several cases of variola being contracted from cases of supposed varicella, cases which had been pronounced varicella by careful and trained examiners.

He had met several cases of varicellous-like eruption, so that, with Gregory, he believed in making a subdivision of varioloid which should include this under the head of variola varicelloides. He was led to this opinion by observing several cases of vesicular eruption closely resembling varicella in persons protected by vaccination, who were in houses where a patient was under

treatment for variola. Another chance for error exists in the fact of the patient coming under observation at that time in the history of a mild variola when the vesicle is full.

At times different forms of skin disease are mistaken for variola; those which are most liable to lead to such a result being herpes, erythema, urticaria, and lichen.

Typhus fever, when well marked, and presenting the characteristic eruption, occasions little trouble in making a diagnosis. The earliest cases of a visitation are, however, not always so well developed, and, in consequence, the disease gains headway, usually in localities most calculated to promote a rapid spread of the disease. In children particularly, there may be great trouble in deciding between typhoid and typhus. Some years ago while typhus was prevailing, an outbreak of fever occurred in an orphan asylum where, out of a number sick, there was absolutely no characteristic eruption. The attendants said that only a few had looseness of the bowels, nose-bleed had not been marked, and the records of fever had been loosely kept; so that it necessitated several days of study before an opinion could be given, with some degree of certainty, that the disease was typhoid fever. This was confirmed by seven autopsies.

If we are able to study a number of cases, we may find the average duration a marked help in diagnosis, especially in adults. A fever, the greater number of cases of which terminate, many of them with comparative suddenness, between the eleventh and fourteenth days, should always raise the suspicion of typhus. An autopsy should invariably be made as a sanitary necessity (should the opportunity occur) to decide the nature of a doubtful outbreak of fever. The lesions of typhoid are characteristic, while those of typhus are in some respects negative; but, in practice, if one of a number of cases of fever which has lasted longer than a week should present on autopsy only an enlarged spleen, with minute hemorrhages on the serous membranes, and parenchymatous degeneration of the liver and kidneys, we would feel justified in considering it due to typhus fever in this climate. Where isolated cases are concerned, an examination of the intestinal mucous membrane and of the muscles should be made, lest the trichinous disease may have passed in one instance as a fever.

Dr. Janeway said he had been much struck by the value of an examination as to the nature of the disease occurring in other inmates of the house or among the friends of a fever patient, as an early help in deciding upon the true cause of a case of fever. This is particularly true of hospital patients, who are often, as a result of the disease, assisted perhaps by congenital deficiency, too stupid to give a good account of themselves. The neglect of resorting to this means of information and diagnosis had been, in several cases in his experience, very unfortunate. As in the case of smallpox, he said he would urge upon the profession the wisdom of oftener resorting to this plan in forming an opinion. The Board of Health would do it on request. He was willing to admit that typhoid fever might occur with typhus, but in practice, two or more persons who had been similarly exposed should, if becoming sick with a febrile complaint nothwithstanding certain differences in the manifestations, be considered as having the same disease. He is particular on this point because, owing to some differences in the eruption and certain minor details, he has at times been told that of two members of a family sick, one had typhus and the other typhoid fever.

It has sometimes been taught that typhoid fever is not contagious, and hence that if several members of a family sicken one after the other, then if the symptoms are not decisive, this contagious nature will point toward typhus. Taken as a broad generalization of city practice, it might be held true, but unfortunately enough exceptions are met with, even in the city, to destroy its full value, while in the country we have the indirect contagion if not the direct, causing several members of a family successively to fall victims to typhoid. He has known the use of antipyrin to cause the appearance of a profuse, somewhat measly rash, which led the medical attendant to suppose that what he had previously considered typhoid was typhus fever. As regards diarrhœa, all practitioners know that not a few cases of typhoid pass through without it, and again, that it may occur in typhus, though the passages do not possess the peculiar color of those of typhoid.

Typhus fever is not alone likely to be considered as typhoid, but also to be mistaken for cerebral inflammation, and particularly for cerebro-spinal meningitis, in consequence of the occasional presence of a petechial rash in the latter. In doubtful cases optic neuritis, if present, would decide in favor of cerebro-spinal inflammation. But, notwithstanding the fact that he had had a considerable experience with cerebro-spinal fever, he had not as yet seen a single case in which the rash resembled that of typhus. In the few cases which he had seen with petechia, it had been more like that seen in some cases of malignant smallpox. Moreover, we very commonly meet herpes of the face and lips in cerebro-spinal disease, but so rarely in typhus and typhoid fever as practically to amount to an almost pathognomonic sign against these affections, if present in a doubtful case. It may occur in so many other affections, however, that its presence is of no diagnostic value, except as against the probability of either typhus or typhoid.

Fleabites occurring in typhoid fever have in some instances caused a diagnosis of typhus. So, again, has a profuse rash in which a number of *taches bleuâtres* of the French were present. He had endeavored, also, to ascertain how far it was probable that pediculi pubis were the cause of this eruption, and he intended to continue the investigation, though it was a matter in which he did not anticipate any great success.

Tuberculosis is a condition which causes not a few mistakes in the diagnosis of typhoid fever, and at times of typhus also. Meningitis is so rare a complication of typhus or typhoid fever that its existence should always raise the suspicion of another process, and more particularly of tuberculosis. If, under these circumstances, choked disk should be found on ophthalmoscopic examination, it would still further increase the probability of this affection. The next step in the diagnosis would be to ascertain if, in any point of the body, there exists a tubercular lesion accessible to proof or strong suspicion, or if from the previous history there is any probability of such a condition in the lungs. It should be borne in mind that the examination of the lungs in unconscious and particularly comatose condi-

tions is extremely unsatisfactory, so that very good examiners have supposed the lungs to be in health when making examinations in those states, while they were, in reality, the seat of far advanced phthisical processes.

If decided proof existed, as a result of a physical examination, that the lungs are the site of disease, which, from its position could be assumed to be tubercular, then it would, with the foregoing facts, be violence to evidence to call the disease typhus or typhoid unless absolute proof of their presence could be obtained, as by the eruption of typhus. Some supposed that the finding of bacilli of tubercle in the sputum would invariably decide the question between typhoid and tuberculosis, as, in cases seen moderately late in the disease without a reliable previous history, a bronchopneumonia of typhoid, and that accompanying certain cases of tuberculosis might be distinguishable by physical signs. Providing that the examination was made with care, and more particularly that every precaution was taken in collecting the sputum, to be certain that there was no contamination of the vessel or of the sputum after collection, then the presence of indubitable bacilli would be proof. But—and this was the point to which he particularly wished to direct attention—if it was supposed that any one could make the examination and decide, and if the ordinary manner of collecting sputum was employed, then there were chances for error.

Again, bacilli might not be found in the sputum from tuberculous patients, because of lack of care in selecting the proper portions for examination, and in some cases as a result of employing the short method for staining. While he had been able to make some very good diagnoses by the employment of these means, he had also met cases in which phthisis had been diagnosticated as the result of the finding of a few bacilli, yet the subsequent course of the disease or an autopsy disproved the diagnosis. There are certain things which a hasty observer might mistake for bacilli, as little crystals which appear red as the light is refracted in passing through them, not sufficiently decolorized bacteria of other kinds, etc. Dr. Janeway had, however, seen both typhoid and typhus coexistent with phthisis.

Pyæmia, and more particularly that dependent upon otitis media, and bacterial thrombosis of the lateral sinuses, caused mistakes in diagnosis, as against typhoid and typhus fever. The reason for this was, that, in the unconscious or delirious state in which patients thus affected are apt to come under observation in hospital practice, no mention was made of the old ear trouble, and no examination of the ear would be made. The irregularity of the fever, the not infrequent coexistence of meningitis or of cerebral abscess, with phenomena more or less strongly suggestive of these conditions, the history or the present observation of suppurative discharge from the ears, and that it had perhaps become foul or been arrested, tenderness or œdema over the mastoid process, and the observation of abscesses in the cellular tissue or of joint inflammation, should at once lead to a diagnosis of probable otitis media. The swelling of the little vein behind the ear and the œdema of the tissue on the mastoids might be absent in severe disease, and present where the subsequent course demonstrated that the process was not pyæmic.

In one instance, of a woman with some severe fever, which had been supposed to be typhoid, Dr. Janeway found as a useful adjuvant to diagnosis thrombosis of the internal jugular vein, giving a firm feel to the vessel. During the present year he had met with three illustrations of this malady, and in one the thrombosis of the lateral sinus was not of a completely obstructing nature, and, in consequence, the œdema behind the ear was absent. In a suspected case jaundice would point toward pyæmia or septicæmia, as distinguished from the fevers in which its occurrence is comparatively rare. Such jaundice was present in one of the three cases just referred to.

The President, after alluding to the injustice which had been done a well-known practitioner of the city in imposing a fine upon him for performing his duty in reporting to the sanitary authorities a suspected case of smallpox, said that within the past three months he had been called to see a child nine years of age in whose case four physicians had already failed to make a diagnosis. The symptoms were very obscure, but resembled cerebro-spinal meningitis more than anything else. There was slight opisthotonos, but no eruption of any kind. The child died within forty-eight hours, and no autopsy was permitted. Within a week a child residing not more than a hundred yards from the last was taken with similar symptoms. He supposed that it was a case of some suppressed eruption, and ordered the child to be placed in a hot pack. As there was marked exhaustion, alcoholic stimulus was also given freely. Within three days measles developed itself, and the patient passed through a violent attack of the disease.

Three years ago he made out the diagnosis of varioloid in the case of a young lady twenty-one years of age. As the attack was a mild one, and there was a possibility of doubt about the nature of the case, he requested that an expert from the Board of Health should be called in, and this gentleman confirmed the diagnosis. Some time later, however, another physician saw the case, and he expressed the opinion that the young lady had had *varicella;* which naturally caused a great deal of disturbance.

Dr. P. Brynberg Porter called attention to the striking resemblance of herpes zoster of the face, when at its height, to erysipelas, and the possibility of making a mistake in diagnosis, unless one had seen the case from the beginning or took special pains to ascertain the exact history of the attack. He related a case in point.

Dr. John Shrady remarked that it is often very difficult to make a positive diagnosis in cases of hemorrhagic smallpox occurring at the beginning of an outbreak of the disease, and recited cases to illustrate this. He also spoke of another class of cases still more obscure, in which the patient has a second attack of the disease.

Dr. Janeway presented the heart and kidney of a patient who had died of

ULCERATIVE ENDOCARDITIS.

He was a salesman, twenty-seven years of age, who had had rheumatism from boyhood, and disease of the heart from at least the age of sixteen. The attack in question came on one week before his death. He had a chill, accompanied and followed by headache and pain in the back and shoulder. On the first day, the

temperature was 103° in the morning, and 104° in the evening. On the next day it was 99° in the morning, and 101° in the evening. On the third day he was affected with muttering delirium, and had epistaxis; the morning temperature being 100°, and the evening, 104°. There was no diarrhœa or abdominal tympanites.

Fourth day: Temp., A.M., 102°; P. M., 103⅘°.

Fifth day: Temp., A.M., 102⅘°; P.M., 104⅘°.

Sixth day: Temp., A.M., 103°; P.M., 104⅗°.

During this time the temperature had been more or less modified by the administration of salicylate of sodium and antipyrin. On the seventh day, on which he died, the temperature was 103°.

In this case there was a strong suspicion of typhoid fever; but when the patient was first seen by Dr. Janeway, on the sixth day, he was much more stupid than a case of typhoid would have been at that stage of the disease. On the forehead, behind the ear, and on the back and abdomen were found a few petechial points. Under the circumstances, he made the diagnosis of ulcerative endocarditis. In addition to a heart murmur, which had previously existed for a long time, a new basic murmur was now detected. On the sixth day, after Dr. Janeway saw him, larger petechiæ or hemorrhagic extravasations developed on the soles of the feet and the palms of the hands.

The specimens presented abundantly confirmed the diagnosis. There had been but one kidney, and that was the seat of numerous hemorrhagic extravasations. On the aortic and mitral valves of the heart there were well-marked vegetations. This case, Dr. Janeway remarked, served to illustrate the possibility of mistaking ulcerative endocarditis for some of the more common febrile diseases.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, May 24, 1886.

THE PRESIDENT, JAMES T. WHITTAKER, M.D., IN THE CHAIR.

A CASE OF ECHINOCOCCUS OF THE LIVER.

DR. JAMES T. WHITTAKER, in reporting a case of this disease, prefaced his remarks with the statement that the rarity of echinococcus in this country makes valuable every clinical report of a case, if only for the purpose of keeping alive the suspicions of the practitioner. For since the days of aspiration the diagnosis of an accessible echinococcus has become extremely simple in the presence of suspicions as to its possible existence in a given case.

Mr. H. P., aged sixty, a tall German, originally of iron frame, began to suffer from dyspeptic symptoms about two years before he came under Dr. Whittaker's observation and visited numerous physicians vainly to secure relief. The first physical examination of his case was made six months before he came under observation, when a fulness was noticed in the region of the right hypochondrium and epigastrium. The symptoms were so plainly and exclusively gastric at this time as to lead to the vague opinion of "stomach trouble" and "dyspepsia."

Mr. P. was a man but little given to notice his own sensations. He occupied an important and responsible position as foreman in a large factory and was steadily busy throughout the day. In fact, he ceased work only on the day that he came to Dr. Whittaker, and then more on account of depression of spirits than from any pain or other cause of incapacity. He had, with increasing debility which he attributed to loss of appetite, become apathetic and indifferent to his work, which had always been hitherto his chief satisfaction. In fact, he had become quite indifferent to life, and consulted another physician only to silence the entreaties of his friends.

He had little or nothing to communicate upon the first examination, though the general emaciation, sluggishness of mien and response, and sallowness of hue bespoke better than words a chronic organic disease. On exposure of the abdomen the tumor mentioned was prominent at the first glance. It was clearly in the region of the liver, the surface of which protruded regularly in every direction. Both lobes were evidently affected, as the outlines reached well over to the left hypochondrium and down to the line of the umbilicus in its most depending part. The edges of the tumor could be grasped by the fingers flexed with pressure into the abdominal walls. There was also surface œdema. It was plain that the tumor was lobular. Two quite large masses, each the size of the double fist, could be readily distinguished, as well as numerous smaller growths. One of these smaller tumors, situated just below the ensiform cartilage, fluctuated distinctly, and a deep, doughy sensation was felt in the larger growths. The multilocular character of the tumor, with the history of its slow progressive growth, and the entire absence of pain or other local distress beyond that of weight and distention, led at once to the conviction that the case was an echinococcus of the liver. With this conviction, Dr. Whittaker introduced the needle of a small stout aspirator about twice the size of an ordinary hypodermatic syringe—in fact, the veterinary hypodermatic instrument—and upon withdrawing it felt disappointed at finding it seemingly empty. But upon pushing down the piston preparatory to returning the instrument to its case he discovered that the barrel of the syringe was full. The fluid, of water-like clarity, had flowed in so easily as to have followed the plunger close on its withdrawal in the process of filling the syringe,

Dr. Whittaker took this fluid, about half an ounce, to Dr. E. W. Walker, who tested it in his presence. The application of heat and nitric acid made no, or almost no precipitate, while the addition of a solution of nitrate of silver threw down a visible deposit of the chlorides. Two rather dubious specimens of hooklets were found on microscopic search. The diagnosis of echinococcus was thus established.

The patient was absolutely averse to an operation. He now passed out of Dr. Whittaker's hands. Two weeks later the patient was bedridden and complaining of pain in the right hypochondrium. This pain disappeared in a few days under rest and hot applications, when he expressed willingness to have the largest sac emptied by aspiration, though he peremptorily refused anything like a radical operation. Accordingly, with the assistance of Dr. Bigney, Dr. Whittaker removed with the Dieulafoy aspirator about a pint and a half of fluid of the same character as the first. It was at this time that he got an indistinct sense of hydatid tremor. With the needle in the sac he now injected a half pint of a strong solution of carbolic acid. This injection was

attended toward its close with such severe pain as to compel the withdrawal of the fluid entirely, and the administration, hypodermatically, of a dose of morphia. This operation was followed by a circumscribed peritonitis, from which the patient recovered entirely only after the lapse of two weeks.

It was evident that the sac punctured had filled up completely, and that the whole mass was enlarging. There now developed considerable œdema of the feet, the interference with digestion became most grave, and emaciation progressed rapidly, with corresponding loss of strength. It was plain that death must soon occur from exhaustion.

The patient finally consented to an operation, more in the hope, as he expressed it, of securing relief even with a fatal issue. The operation was performed by Dr. Conner, whom the speaker invited to report the operation.

Dr. P. S. Conner stated that at his first examination of the patient there could be no question that a cystic tumor of the liver was present. There were two large masses recognizable, one seemingly in the right lobe of the liver, the other in the left; the smaller tumor to the left appearing to rest upon the larger to the right. Whatever may be said as to the propriety of operative measures now, there could be no question then that after a part of the fluid had been removed by aspiration and the sac had refilled, an incision was imperative. He cut down upon the liver, making the incision parallel to the long axis of the liver, about two inches in length. The peritoneum was incised, the surface of the liver exposed, and after stitches had been inserted so as to bind the cyst-wall firmly to the abdominal wall, he made an incision into the cyst with the knife. Pushing in the knife, he expected to find the fluid very quickly, inasmuch as the insertion of the hypodermatic needle had so readily withdrawn fluid, but he had to cut down an inch and a half before he reached the fluid. For three-fourths of the time that the man lived after the performance of the operation his condition steadily improved from day to day; but for forty-eight hours before his death he became weaker and weaker, until he finally passed away.

The examination of the tumor, after removal, proved positively that no operation could have been of any benefit. At least twenty-five large cysts were found, and a great many more of smaller size. Fortunately, hydatid cysts are usually single, or there are at most two or three cysts lying closely together. Where the latter condition is found, surgical procedure promises better results than where there are several cysts, or a great many, as in the case under consideration.

GENESIS OF ECHINOCOCCUS.

Dr. R. W. Stewart, in opening the discussion of this branch of the subject, remarked that he would confine himself to the theory and explanation of the birth and production of the echinococcus.

Probably no class of diseases, no pathological new growth, no microörganism has ever given such apparently complete and perfect support to the theory of spontaneous generation as that formerly known as hydatid disease, and now known as echinococcus cyst, for here was a growth in a closed sac within a closed organ, completely shut off from the external air. It grew, and had no counterpart in the outside world. Ova were sought for but were never found; organs of generation were sought for when no such organs existed. There could be nothing else but spontaneous generation until Steensteup, in 1842, made his observations upon the cercariæ, and discovered that "some of the entozoa, by a non-sexual process, undergo that peculiar form of multiplication in which the immediate progeny of development from the ovum is dissimilar from the parent, but produces without the aid of sexual organs another progeny which either itself or by repetition of an analogous process returns to the parental form" (Allen Thompson). This process is called alternate generation, or metagenesis, and is beautifully demonstrated in the transformations from tænia echinococcus to echinococcus cyst, and from this again to tænia echinococcus. Spontaneous generation receives its death-blow from the very thing which formerly appeared to give it its most prominent support.

The echinococcus is the larval state of the tænia echinococcus, the family history of which may be traced out from the tæniada to the scoleida, radiata, invertebrata (Huxley).

The tænia echinococcus, one of the smallest of our animal parasites, measures about four millimetres in length, and consists of a head and three segments. The last segment contains both organs of generation, and is probably a self-fertilizer. It is larger than the other parts of the worm taken together, and after fructification contains probably five thousand eggs, each of which contains an embryo. The mature tænia does not interest us further in this connection apart from the fact that shortly after fecundation the last segment drops off from the worm and finds its way into drinking water or upon green or ripe vegetables, and is then taken into the stomach of man or other animals, while a new segment is developed in its place and goes through the same process. The separated segment may burst in the intestine of the dog and the freed ova be deposited with the feces in the manner mentioned. When an ovum reaches the human stomach its dense, tough, oftentimes calcareous husk or shell is dissolved off by the action of the gastric juice, and a fully armed embryo carrying six hooklets and about three times the size of a human blood-corpuscle, is set free. This embryo is simply a vesicle or bag with spikes arranged about one end. It bores its way through the stomach wall or may pass down into the intestine and bore through that, or make its way through the ductus choledochus or into the portal vessel, and may thus reach the general circulation and be carried to any organ. The process of growth or development through which it goes after reaching the liver will best answer our purposes of demonstration. The embryonic vesicle after reaching the liver substance increases in size, but does not begin to proliferate for from two to five months. This growth consists in the formation of one large cyst, with walls containing various concentric layers and an outside sheath which is formed from the liver substance. The innermost layer is granular in character and covered internally with ciliated epithelium. This layer becomes thickened in places and gradually forms hollow elevations—the brood-capsules—or it may throw up these elevations and produce out of them daughter cells which, in turn, are to all intents and purposes like the mother-cyst, and

which go through the same process of proliferation, as follows: From the surface of the capsule glove finger-like processes project into the brood-capsule. These are the scolices, the first formation of the head of the future embryo. From this description it will be seen that a scolex is simply a hollow in the brood-capsule, communicating with the general cavity of the cyst and projecting into the brood-capsule.

The scolex soon begins to show at its free end a double row of hooklets and four suctorial prominences to form the head of the embryo. After a time a constriction appears just behind the suckers, and this constriction becomes thinned out into the neck. So long as the scolex remains attached to the capsule-wall, and the constriction is not too great, it can turn itself inside-out and project then not into the brood-capsule, but into the general cavity of the mother cell. This is the course as found in the lower animals; usually, however, in man, the inner or granular layer develops into a number of daughter cells, which protrude into the general cavity of the mother cell—endogenous growth—producing thus the peculiar aggregation of grape-like bodies so characteristic of hydatids. The process of development in the daughter cells goes on just as was described for the mother cell.

The daughter cells vary in number from very few to several thousands, and each brood-capsule contains nine or more embryo.

We have now traced the echinococcus from the ovum to the scolex of the encysted parasite, and have found that the scolex is the embryo, and consists of head and neck. The question naturally arises, How do these embryos develop into the mature worms? If the cyst remain in the body the embryos remain alive as long as they are attached to the cyst wall, or rather to the wall of the brood-capsule. Very little if any further development takes place, except perhaps a slight transverse marking to show the boundaries of the future segments. If, however, the organ in which this cyst exists be eaten by an animal in the intestinal tract of which development can take place (and as yet the dog and wolf are the only ones in which this can occur), the head resists digestion in the stomach, passes into the duodenum, affixes itself to the mucous membrane and then develops into the mature echinococcus.

If the cyst remain in the liver or other organ of the host the embryos develop, as already described, in the brood-capsules and either die and become cast off into the cavity, or they, in turn, develop into daughter cells and produce embryos, and thus make the process an almost continuous one, and one of which the limits of growth are the limits of the organ and its surrounding tissues.

Dr. A. G. Drury said that the tænia echinococcus is the smallest of all the tapeworms, not exceeding a quarter-inch in length, and having four segments, including the head. The last segment exceeds in length all the rest of the worm. It is the only one having reproductive organs; and these include both the male and female organs. There is still some doubt as to the manner in which the female organs are impregnated. Leuckart thinks it is effected by the male organs of the same joint, others suppose that two joints come into contact and are mutually impregnated. It does not appear that the ova are ever discharged through the vagina. They are too large to pass in that way. They remain in situ until the joint is ruptured. This may happen within the intestine of the animal, or after its discharge from the bowels. This tapeworm is found only in the dog, wolf, and fox. It produces thousands of eggs. Within the egg an embryo is formed which is a globular body, provided at one part of its circumference with six delicate hooks, arranged in pairs. This is enclosed in a thick shell which, in some species of tapeworm consists of several layers. These eggs cannot get beyond the embryonic stage in the body of the dog. The eggs are passed with the feces, which become dry and crumble into dust, and the eggs adhering to the dust are blown into gardens and orchards and become attached to vegetables and fruits, much of which is eaten unwashed and uncooked. The echinococcus cysts are developed from these six-hooked embryos. They are found in the lungs, kidneys, bladder, bones, neck, and other parts of the human body, though much more rarely than in the liver. When a man or other animal swallows the ova the shell is dissolved by the digestive juices and the embryos escape. They then bore their way through the coats of the digestive canal, and getting into the bloodvessels are floated along with the current to the liver or other organ suitable to their development.

The reason for the greater frequency of hydatids in the liver probably is that the embryo in boring through the walls of the intestine or stomach generally gets into the rootlets of the portal vein, and is carried into the main trunk and arrested in one of the capillary branches within the liver. Here, again, it probably bores its way out of the vessel into the surrounding tissue where it is eventually arrested. Having reached its permanent home it begins a new stage of development. It loses its hooks, becomes larger, and from being solid becomes a vesicle containing a transparent fluid. From this time it presents the character of a more or less globular vesicle or bladder. Before its relation to the tænia echinococcus was known, it was called the bladder-worm. It gives rise to changes in the surrounding tissues. It becomes surrounded by a layer of granular matter which is an exudation from the tissues of the host; and soon after by a fibrous layer abundantly supplied with vessels. Henceforth the hydatid is always enclosed in this membrane, which is termed its capsule. This capsule grows with the growth of the contained hydatid, fitting closely to its exterior and giving it the support it needs. It is from the vessels of the capsule that the embryo is nourished. After a time the growing vesicle begins to show a projection from some part of its inner surface, and this gradually increases in size and becomes pear-shaped. Soon four suckers make their appearance in the interior of this body and sometimes a circle of minute hooks. After a time a kind of neck is developed. It then looks like the head of a tapeworm suspended within the bladder or vesicle. Up to this point the development of an echinococcus is the same as that of the cysticercus. The further steps are different. The cysticercus, in order to complete its development, would have to form only a single head in its interior. This head would grow as a kind of bud or protrusion from one part of the interior of the cysticercus, and would gradually become provided with its two rows of hooklets and suckers. In the echinococcus, instead of a single protrusion, a number of them form at differ-

ent times from the interior of the animal. Each of these buds does not form a head, but itself becomes a cystic body, which for a time is attached by a pedicle to the spot where it started, but soon becomes detached. This is called a daughter cyst. Each daughter cyst may develop one or more granddaughter cysts in its interior. In this way the echinococcus becomes filled with a number of smaller vesicles of various sizes which may amount to thousands. It will be observed that the difference between a cysticercus and an echinococcus is that, whereas the former gives rise to one head, and can ultimately form a single tapeworm only, the latter may develop thousands.

Sometimes, though exceedingly rare in the human subject, instead of budding internally to form daughter cysts, it forms external protrusions. In this way the liver may become riddled with hydatids not contained in any mother-cyst, but penetrating the liver in all directions.

(*To be continued.*)

CORRESPONDENCE.

THE MUNICH MEETING OF THE GERMAN GYNECOLOGICAL CONGRESS.

The session opened at Munich, on June 16, 1886, with a social gathering in the Hall of the Kunstgewerbe House, at which about fifty prominent gynecologists were present, and the regular business commenced on the morning of the next day at 10 o'clock, in the clinic room of the maternity. Sixty members were then present, and the chair was occupied by Prof. Winckel, Prof. Küstner acting as Secretary. Among those present were Prof. Kaltenbach, of Giessen, Prof. Müller, of Berne, Prof. Fehling, of Stuttgart, Prof. Schatz, of Rostock, Prof. Winckel, of Munich, Prof. Küstner, of Jena, Dr. Sänger, of Leipzig, Prof. Credé, of Leipzig, Prof. Scanzoni, of Würzburg, Prof. Olshausen, of Halle, Prof. Slavyansky, of St. Petersburg, Dr. Frommel, of Munich, Dr. Kehrer, of Heidelberg, Dr. Krukenberg, of Bonn, Dr. Skutsch, of Jena, Dr. Stumpf, of Munich, Dr. Veit, of Berlin, Dr. Hofmeier, of Berlin, Dr. Freund (the younger), of Strassburg, Dr. Elischer, of Buda-Pest, Dr. Donat, assistant to Prof. Credé, and many other faithful workers in the gynecological field. Prof. Paul F. Mundé, of New York, and the writer, were the only representatives not of the Continent of Europe.

The meetings throughout were most admirably conducted by the ready judgment and excellent tact of the chairman, Prof. Winckel. In looking over the assembled heads only two were gray, one belonging to the still wiry figure of Herr Geheimrath Credé, and the other to the portly one of old Prof. Scanzoni. Many of the others, whose names are already well known abroad, are young men.

Prof. Winckel, in opening the meeting, extended a cordial welcome to all the members, particularly those who had come from great distances; he alluded to the recent sad death of the King of Bavaria, and stated that had there been time to notify the members the meeting would have been postponed, both out of respect, and because the whole town was at present in mourning.

Prof. Müller, of Porro-Müller reputation, then delivered the first address. No essays were read, the members either using brief notes, or speaking entirely from memory, and their delivery was for the most part energetic and impressive. Prof. Müller spoke upon the "After-treatment of Grave Laparotomies." He referred to shock, embolism, and coprostasis, but considered one of the greatest of all dangers to be extensive adhesions of the intestines to areas of the anterior abdominal wall which had been extensively denuded. To avoid this he advised a forced injection of a sterilized salt solution into the peritoneal cavity so as to keep a water-pad on the raw surface until it should glaze over, when the water was to be let out again.

Prof. Schatz stated his belief that adhesions were much more common than believed, and considered the use of opium contraindicated.

Prof. Kaltenbach said that adhesions were, in times past, vastly more common, being due to imperfect toilet, and often to abrasions of the epithelium by the cleansing sponge. Since using the bichloride he has seen no adhesions.

Dr. Sänger said he believed adhesions were the rule, that they do no harm, and that injections will not prevent them.

Prof. Müller replied that he always used sublimate solutions and had adhesions in spite of them.

Dr. Bayer, of Strassburg, then delivered a finished address upon "Placenta Prævia," containing many new theories of his own elaboration which provoked some active opposition on the part of the members.

Dr. Frommel, of Munich, delivered an address upon the "Histology of the Fallopian Tube," which was well illustrated by plates and slides; he had devoted special attention to the epithelium, and to the development of the plica.

Prof. Fehling, of Stuttgart, brought before the members the results of a critical study of the "Relation between the Amount of Hæmoglobin in the Amnion and in the Mother's Blood," showing a constant relation.

Dr. Sänger next introduced to the attention of the Society a new field for pelvic exploration, the "Palpation of the Ureters, with Demonstrations." He showed that the examining finger in the vagina could feel one or both ureters in about eighty per cent. of all cases, and in a much larger percentage of pregnant women, and that in pyelonephritis such a demonstration often determined a one-sided thickening, and a ureteritis pointed distinctly to the affected side, as he had in several cases proved. Prof. Winckel furnished six pregnant women for a demonstration, which was made to the satisfaction of all present.

Prof. Kaltenbach exhibited some hypertrophied ovaries, and a uterus four and a half months pregnant, with a myoma as large as a cocoanut.

He also delivered an address upon the subject of "Prophylaxis of Ophthalmoblenorrhœa of the Newborn." The percentage of disease in neglected cases he stated to be enormous. To insure protection he combines two methods, both cleansing the vagina and washing the eyes of the child in a sublimate solution.

Prof. Olshausen considered the nitrate of silver solution by far the best. In two hundred cases so treated, he had had but one one slight catarrh, and that was innocuous.

Prof. Leopold, of Dresden, spoke of the technical difficulties in effectually cleansing either vagina or eyes.

Prof. Credé, speaking from his enormous experience, had had perfect results from the use of the nitrate of silver solution; in two years in the Leipzig Lying-in Hospital they had had but one case of ophthalmoblenorrhœa.

Dr. Stumpf, of Munich, delivered an excellent address, being a digest of a series of well-studied cases of puerperal convulsions.

Dr. Sänger's paper on the "Relation of Gonorrhœal Infection to Puerperal Diseases," was again a most valuable contribution, showing that latent gonorrhœa may produce no serious evidences of its presence until after childbirth, when an active peritonitis or pyosalpinx may quickly arise. He considers gonorrhœa a most frightfully common malady, and for diagnosis rests upon clinical features, the coccus being an utterly uncertain and unreliable point. In tracing back one suddenly arising puerperal peritonitis, he found that one of the children had had ophthalmia, and that the husband had had gonorrhœa.

Dr. Gräfe, of Halle, cited a case from his private practice.

Prof. Kaltenbach had traced a case through an intervening endometritis.

Dr. Sänger does not believe that endometritis is a necessary or usual preliminary.

Dr. Bumm insisted that the diagnosis of gonorrhœa could not with any certainty be established until the coccus had been found. He claimed that all types were mimicked by catarrhs, and insisted further upon the ease with which the microscopic examination could be made. The gonococcus is only found very superficially in membranes; the coccus found in glands and abscesses is the staphylococcus aureus.

Prof. Winckel made some remarks as to the negative nature of culture-work and experimental pathology in this direction.

The meeting then closed for the first day, with the announcement that the next meeting would be held in two years in Halle, with Prof. Olshausen in the chair, and the following members, now present, as officers, Profs. Gusserow, Schatz, Kaltenbach, Küstner, and Schwartz.

On Friday morning, June 18th, the meeting reopened with an address from Dr. Elischer, of Buda-Pest, on the "Use of Iodoform in Laparotomy." He considered this a dangerous agent, and one not to be used in the abdominal cavity. The members in reply disagreed with the speaker entirely.

Prof. Olshausen considered a dusting of iodoform a most valuable expedient in cases of tubercular peritonitis.

Prof. Schatz, of Rostock, made a novel address upon "Sores of the Bladder and their Cure." He cited a case where he cut down into the bladder above the pubes, cut out a "sore" and brought the resected parts together, thus attaining a successful result.

Dr. Zeiss, of Erfurt, detailed some cases of Alexander's operation, which provoked a general discussion, and a very interesting reply from Prof. Mundé. Sufficient time, however, had not elapsed since Dr. Zeiss's first case, and the constant necessary (?) use of a pessary was regarded with much suspicion.

Prof. Mundé stated that where he had succeeded perfectly in finding the ligaments, his results had been typical. He considered the operation one of great value in a limited field.

Dr. Skutsch exhibited a "New Instrument for Obtaining Measurements of the Internal Oblique and Transverse Diameters of the Pelvis." It consists of a board, fastened to the pelvis by straps resting upon the pubes and the anterior superior iliac spines. Just over the pubes are two sockets which receive two long fingers of lead. In use, one of these fingers is attached to a socket, and is then carried by its free end upon the index finger up into the pelvis and pressed high up against the ileo-pectineal line. The lead retains the curve impressed upon it on being removed, the same is done with the other finger of lead for the other side. The apparatus is then removed, the fingers are reattached, and the transverse pelvic diameter is the distance between the free ends.

Prof. Küstner then exhibited a pair of tongs like old hair-crimpers, which are intended to be carried high up in the vagina and separated, an arc at the handles indicating the divergence and, therefore, the diameter in question.

Dr. Firnig then narrated a case of Cæsarean section and exhibited the pelvis which was extremely narrowed by rachitis.

The number of addresses to be delivered on Saturday was so large, that no discussions were allowed, and the members were obliged to time themselves.

Prof. Küstner brought before the meeting his results in the "Treatment of Lacerated Perineum by Different Methods," with an estimate of the relative value of the various procedures. He spoke particularly of the operations of Hegar, Freund, Simon, Bischoff, Winckel, and Fritsch; he also detailed some interesting experiments with a twenty per cent. solution of hydrochlorate of cocaine on three cases.

Prof. Olshausen next spoke of the "Nutrient Value of the Amnion."

Dr. Wyder's address was upon the "Changes in the Uterine Mucosa Consequent upon the Presence of Submucous, Subserous, and Interstitial Myomata Respectively." He exhibited some interesting drawings and sections.

Dr. Hofmeier, of Berlin, presented three very interesting specimens to the Society. 1. A tubal pregnancy in the second month. 2. A uterus with large subserous myomata successfully removed. 3. A uterus from a case of eclampsia showing contraction ring.

Prof. Schwartz spoke upon the total extirpation of the uterus for cancer: Dr. Battlehner, upon the healing of cervico-vaginal lacerations.

In conclusion, Prof. Credé moved that the Society express its most cordial approval of Prof. Winckel's efforts in inviting and accommodating the members, and that they should signify their assent by all rising, which was done. The Society then adjourned for two years. Most of the members remained in the city the rest of the afternoon to witness the funeral of King Ludwig.

Howard A. Kelly, M.D.

Leipzig, June 23, 1886.

NEWS ITEMS.

VIENNA.

(From our Special Correspondent.)

The Appointment of a Successor to Professor Spaeth.—Medical men in Vienna have been awaiting

with interest the announcement of the appointment of a successor to Professor Spaeth, in the second clinic for obstetrics. As candidates, were mentioned Prof. Gustave Braun, who has charge of the third clinic—that for midwives—and also Prof. Breisky, from the Lying-in Hospital of Prague. The first-named candidate was supported by the influence of his brother, Carl Braun; the second by some others of the hospital Faculty. After a shorter time than is usually given to the consideration of such appointments, the Emperor and the Ministers returned the name of Prof. Breisky, quite to the surprise of many, who thought the influence of Carl Braun sufficient to secure the appointment of his brother. The Prague Clinic has a beautiful building, and is in fine condition, and Prof. Breisky has been most successful in his teaching and practice. He will be welcomed to Vienna by many friends and admirers. Prof. Spaeth was retired with abundant honors, including a decoration from the Emperor. As a friend and follower of Semmelweiss, he was one of the first to recognize the value of the latter's theory regarding puerperal sepsis, and his influence and work have been on the side of conservative midwifery. His clinic has at present attained as high an order of excellence as is possible in so old a building with the present system of attendants and the large number and character of patients. This result is owing to the personal attention of the assistants, and the following statistics of the year 1885 may prove of interest, as showing the results obtained in this clinic:

Number of births	2761
Labors ending spontaneously . .	2456
Abnormal labors	305
Percentage of septic deaths, $\frac{57}{100}$ths of 1 per cent.	

This is but one-third of the material in the Vienna Hospital, the remainder being divided between the brothers, Professors Carl and Gustave Braun.

THE AMERICAN NEUROLOGICAL ASSOCIATION will hold its annual meeting at the Howland House, Long Branch, N. J., on Wednesday, Thursday, and Friday, July 21, 22, and 23, 1886. Two daily sessions will be held, one in the morning from 10 A.M. to 1 P.M., and one in the afternoon from 3 to 5 P.M.

THE AMERICAN OTOLOGICAL SOCIETY will meet at New London on Tuesday, July 20th.

THE AMERICAN OPHTHALMOLOGICAL SOCIETY will meet at New London, on Wednesday, July 21st.

AN INTEMPERATE ABSTAINER.—An unfortunate teetotaller some months ago attended a temperance lecture, and was there informed that ammonia was the best substitute for alcohol. Having a pain in the chest, he took a tablespoonful of the drug, which caused his death after great agony. At the inquest the jury returned a verdict of accidental death.

ABSENCE OF RABIES IN BUENOS AYRES.—In an article published in the *Revista Med. Quirurg. de Buenos Ayres*, Dr. J. Franceschi states that no case of rabies has been observed in that province during the past fifteen years, although the proportion of dogs kept there is larger than in any European country. He believes that rabies may be produced idiopathically in dogs by feeding them on vegetable food exclusively. In Europe meat is scarce and hydrophobia correspondingly common, but in Argentine Republic meat is the common food of dogs, and hydrophobia is unknown.

A NEW LUNATIC ASYLUM is to be established in the northern part of the State of New York. Among the commissioners appointed to choose its situation are Dr. P. M. Wise, of the Willard Asylum, and Dr. J. M. Cleveland, of the Hudson River State Hospital at Poughkeepsie.

THE YALE MEDICAL SCHOOL.—It is announced that Dr. James Campbell, of Hartford, has been appointed Professor of Obstetrics.

THE UNIVERSITY OF VIRGINIA.—Dr. W. B. Towles has been elected Professor of Anatomy.

PERSONAL ITEMS.—Dr. Louis A. Duhring, of Philadelphia, and Dr. Joseph W. Howe, of New York, sailed for Europe on Saturday, the 26th ult. Dr. Fordyce Barker, of New York, Dr. John S. Billings, U. S. A., Dr. James R. Chadwick, of Boston, and Dr. H. P. C. Wilson, of Baltimore, sailed on Thursday, July 8th.

LAFAYETTE COLLEGE, of Easton, Pa., has conferred the degree of LL.D. on Dr. Henry D. Swift, of the University of Pennsylvania, and the degree of A.M. on Dr. J. Clinton Edgar, of New York.

SIR JAMES PAGET has just been elected a foreign associate of the Academy of Medicine of Paris, by 57 votes out of 64. Dr. Charles West, of London, and M. van Beneke, of Brussels, were the other candidates.

A PASTEUR INSTITUTE IN MILAN.—Milan is the first of Italian cities to turn M. Pasteur's experiences to practical account. Dr. Barattieri has returned to Milan from Paris, after having spent three months at the Pasteur laboratory, where he has been well initiated into the orthodox method of combating hydrophobia, taking with him a quantity of virus and several of the animals already operated upon by the great French scientist. After a consultation between the directors of the Scuola di Veterinaria and others, it has been decided to found a Pasteur Institute in Milan, the expenses of which are to be defrayed by the municipal authorities and the Government. Meanwhile, Dr. Barattieri has been accommodated with a temporary laboratory, where he is to commence active operations in the course of a week or two. Dr. Ullman, of the University of Vienna, who has also spent several weeks in the laboratory of M. Pasteur, has returned, taking with him some of the virus with which he proceeded to inoculate his first batch of patients, consisting of thirteen men and one woman, all said to have been bitten by rabid dogs.

PROFESSOR VIRCHOW recently completed the thirtieth year of his occupancy of the chair of Pathological Anatomy at Berlin.

DANGERS OF PERAMBULATORS.—Dr. Maclagan, the medical officer of the Hexham Rural Sanitary District, England, while calling attention to the fact that in his

district 124 children out of 1000 die during their first year, attributes much of the mortality to "inflammatory diseases, cerebral and pulmonary," caused by exposure in perambulators. Dr. Taylor, of Scarborough, also lays much stress on the matter of wind-pressure to which the perambulator exposes children, in the causation of diseases of the throat and chest.

Honors to Dr. Dalton.—The degree of LL.D. was conferred upon Dr. John C. Dalton, President of the College of Physicians and Surgeons, New York, by Princeton College, at its recent commencement.

Scientific Sewerage for Philadelphia.—At a meeting of the Board of Health of Philadelphia a few days ago a petition was presented by Dr. Ford from a number of citizens, who he stated represented over a hundred millions of dollars, in favor of an improved sewerage system, and offered the following, which was unanimously adopted: "*Resolved*, That the Board of Health of Philadelphia earnestly request City Councils to give prompt and favorable consideration to the petition of citizens praying for the authorization of a thorough scientific investigation of the sewerage system of the city, with the object of discovering and correcting the radical faults connected therewith."

Election of Dr. Brown-Séquard to the Academy of Sciences.—Dr. Brown-Séquard was elected a member of the Paris Academy of Sciences at its last meeting on June 21st, in the Section of Medicine and Surgery. The eminent biologist was elected by a large majority, and the victory was the more creditable as the competitors of Dr. Brown-Séquard were all men of note, in proof of which statement may be mentioned the names of Germain-Sée, Bouchard, Jaccoud, Hayem, and Richet.

Spontaneous Transformation of Morphine into Apomorphine.—A solution of hydrochlorate of morphine for subcutaneous injection (three per cent.) was ordered for a patient, and its injection was promptly followed by relief of the pain, without any gastric symptoms whatever. Eleven months later, the patient made use of the same solution; but, this time, the injections gave rise immediately to violent and uncontrollable vomiting. The solution was given to a well-known analyst at Paris for examination, and he ascertained that apomorphine was present, thus accounting for the sickness. He recommended, in consequence, that solutions of the salts of morphine should never be kept longer than four weeks, and that freshly prepared solutions should not be mixed with the old.

Mode of Payment of Fees in Vienna.—In Vienna it is usual to give medical men their fees at the end of the attendance, so that when honoraria are offered the hint is understood and no more visits are paid without further request. Some time since a practitioner was sent for to see the child of a certain tailor, whom he found suffering from fever, but with no signs enabling a diagnosis to be made. The fee was given, and the doctor hearing nothing further, did not consider his services were required again. However, it was discovered by the police, shortly afterward, that some of the children in the tailor's house were suffering from smallpox. The tailor and the doctor were both summoned, the latter being acquitted, while the former, who was shown not only to have concealed the existence of the disease, but to have taken in work at the time, was sentenced to ten days' imprisonment.

Poisonous Gloves.—The *Provincial Medical Journal* says: "We have recently had several cases of a peculiar herpetic eruption about the lips of children, and which we have satisfied ourselves were due to cheaply dyed gloves. The children wearing these gloves rubbed their mouths with them. The rash could be produced at will. When the gloves were taken off and not worn for some time, there was no rash. When, on the other hand, the gloves were worn, and the children repeated the practice, the rash returned. Clearly it was a case of cause and effect. Owing to competition, manufacturers endeavor to cut down the expenses of production by using the cheapest form of dye; and the public support them by buying cheap products."

NOTES AND QUERIES.

CATGUT SUTURES FOR OPERATIONS UPON THE LACERATED CERVIX UTERI.

To the Editor of The Medical News.

Sir: In The Medical News for July 3, 1886, Dr. Sutton gives the history of fifty cases of lacerated cervix which were operated upon by him, and in which silkworm gut was used as the material for sutures. There can be no doubt that silkworm gut is better than silk, and that silk is better than silver wire; but why is it that gynecologists persist in using *sutures which must be removed?* General surgeons wash out the vagina with peroxide of hydrogen solution, or with bichloride of mercury solution, insert sutures of antiseptically prepared catgut, sprinkle iodoform over the vaginal mucous membrane, and make no calculations for disturbing the sutures again until another laceration occurs.

Robert T. Morris, M.D.

New York, July 10, 1886.

PIG-BACKED KIDNEY, A CORRECTION.

To the Editor of The Medical News,

Sir: I notice an error in the report on my remarks on the "pig-backed" kidney of alcoholism, read before the Association of American Physicians, and published in your issue of July 3, 1886, page 18. You would greatly oblige me by inserting in your columns this correction:

"The kidneys, in sudden death from typical alcoholism (a cyanotic induration designated from its shape as the *pig-backed* kidney) are one-third to one-half *larger*, and sometimes double their normal size;" instead of, "is one-third to one-half its normal size," as the reporter gave it.

Very respectfully yours,
H. F. Formad.

ORIGINAL LECTURES.

POLIOMYELITIS ANTERIOR CHRONICA.

An Abstract of a Clinical Lecture.

BY JAMES STEWART, M.D.,

PROFESSOR OF PHARMACOLOGY AND THERAPEUTICS IN MCGILL UNIVERSITY, MONTREAL; AND DIRECTOR OF THE UNIVERSITY CLINIC FOR DISEASES OF THE NERVOUS SYSTEM.

By chronic poliomyelitis is to be understood, not the acutely beginning poliomyelitis which has become chronic, but that form of myelitis of the anterior horns which is essentially a chronic affection from its very commencement.

It is well known that the onset of acute poliomyelitis, or what is more commonly called infantile paralysis, is very sudden. A child goes to bed well, or is perhaps a little feverish; in the morning one limb, or perhaps a single muscular district of a limb, is paretic. In a few hours the paresis becomes paralysis, while at the same time other muscular districts become rapidly weak, and soon powerless. In the course of two or three days the disease has reached its full extent. If any change takes place afterward, it is one toward recovery. In chronic poliomyelitis the onset is very gradual, and is not attended by any general febrile disturbance. The disease creeps slowly along, taking weeks, and even months before an apparent weakness becomes a decided paresis or paralysis.

In the acute disease we are safe in saying that after the third or fourth day there will be no increase in either the extent or degree of paralysis, but in the chronic variety there is no telling when it will come to a stand-still.

The little patient before you is four years of age. She first came under my observation two years ago at the University Dispensary, when she was suffering from complete paralysis of the muscles of the legs and feet.

The child was in perfect health up to the end of her first year, being able to walk and run about with greater alacrity than children generally do when twelve months old. At this time she was taken ill with a severe chronic diarrhœa, which lasted for four months. During the latter four weeks of the course of this trouble, the mother began to notice that she did not move either lower limb as freely as she formerly did. This weakness of the lower extremities slowly increased, but it was fully three months before it had developed into a complete paralysis.

She is the youngest of eight children, five of whom are living and three died in infancy. The cause of death in two was diarrhœa, while the third died from bronchitis. Father and mother are living and in good health.

State when she came under observation two years ago.—There was complete paralysis of the muscular districts of the feet and legs supplied by the crurals, and paresis of those innervated from the lumbar plexus. Flexion and extension of the knee-joints were very imperfect. The hip-joint movements were also very limited.

She did not at that time complain of any pain in her lower limbs or elsewhere, nor had there been any symptom of suffering from the beginning of the trouble. The paralyzed muscles were soft and flaccid. There was considerable atrophy of the paralyzed and paretic muscles. The thigh muscles were, however, of fair volume. There was an entire absence of both the patellar and plantar reflexes.

There was complete loss of the faradic irritability of the nerves and muscles of the lower limbs.

There was no response from galvanization of the nerves of the lower limbs, but there was slow contraction of the muscles when they were directly galvanized. There was, however, no change in the normal electrical formula: the KSZLAOZ.

There was no interference with the functions of the bladder and rectum.

There was no motor or sensory disorder of the upper extremities.

The child continued in the state just described for some two months after coming under observation. During this period no treatment was instituted, except the internal use of arsenic.

The proper treatment of the case was commenced about two months after her condition had remained stationary for several weeks. It consisted in the use of galvanism, the anode (labile) being applied to the lumbar region, and the cathode (stabile) to the muscles and nerves of the lower extremities.

Progress.—After two months of the above treatment, the first traces of returning motility were observed in the peroneal districts. In the course of four months, she was able to flex and extend the toes freely, and shortly afterward she was able to stand with the aid of a chair. At the end of the sixth month of the treatment she was able to stand without any support. She has continued to progress to recovery, but very slowly, however.

Present state.—As this patient walks across the arena, you will notice that she does so without any dragging of her legs. The toes are turned outward, but this is the only sign of deficient motility, and as this abduction is steadily decreasing it is not vain to hope that before long it will completely disappear.

The muscles are of good volume. There is neither contracture nor undue flaccidity.

The patellar reflexes of both legs have not as yet reappeared, although at times there is a perceptible contraction of the left quadriceps when the patellar tendon of that side is percussed.

The modified reaction of degeneration which was formerly present has entirely disappeared. For the past six months the muscles and nerves of both limbs respond to the induced current, and since this has taken place the treatment has been mostly carried out by the use of this form of electricity.

Diagnosis.—Of the nature of this case there can, I think, be no question whatever. It is one of *spinal atrophic paralysis* of the muscles of the lower limbs, of very slow but progressive development, and due to a chronic myelitis (?) of the anterior cornua. The presence of the reaction of degeneration with the loss of the patellar reflexes, and the absence of all disorder of sensation and the non-involvement of the sphincters, prove conclusively its nature.

The symptoms may be classified as follows:

1. Positive:
   - *a.* Diffuse paralysis.
   - *b.* Atrophy of the paralyzed muscles.
   - *c.* Loss of the patellar reflexes.
   - *d.* The presence of the reaction of degeneration.
2. Negative:
   - *a.* Entire absence of sensory disorders.
   - *b.* No hypertonus.
   - *c.* Non-involvement of the sphincters.

A paralysis of central origin is excluded on account of the absence of the patellar reflexes and the presence of the reaction of degeneration. A general neuritis of the lower limbs is also excluded by the absence of any disorder of sensation and the diffuse distribution of the paralysis.

The morbid process commenced in the nuclei of origin of the sacral plexus, and very slowly ascended so as to involve the nuclei of the lumbar plexus. The latter were later and less severely affected than the former.

In the present state of our knowledge it is difficult to determine the exact character of this morbid process, and in what way it differs from the acute affection of the anterior cornua.

The case is remarkable as occurring in so young a patient. Chronic poliomyelitis is not an infrequent disease of adult life, but it is very rarely seen in children under three years of age. The acute affection is, however, essentially a disease of childhood, its occurrence in adult life being very uncommon.

The case may be briefly summarized as follows:

A child about eighteen months of age, who has been troubled with diarrhœa for four months, gradually but completely loses all power to move her lower extremities; regains this power almost completely in the course of a year and a half, while being treated by galvanism.

The favorable result in this case was looked for and promised; this prognosis being based on the published experience of Erb, Hughes Bennett, and others.

Nearly all the recorded examples have eventually recovered, and it is in this favorable ending that we have another marked difference between acute and chronic poliomyelitis. In the former no improvement can be looked for after the sixth month, while in the latter a complete cure is the rule.

ORIGINAL ARTICLES.

A CASE OF TYPHOID FEVER COMPLICATED WITH ABSCESS OF THE LIVER; AND SOME REMARKS ON THE ROSEMONT OUTBREAK OF 1885.

BY GEORGE S. GERHARD, M.D.,
OF ARDMORE, PENNSYLVANIA.

W. H., æt. twenty-six, born in Wales, a gardener by occupation, is a well-built man of large frame, and one of a family of five brothers, an only sister having died of phthisis. His parents are living and in good health, and his own health was always good until the autumn of 1881, when he had an attack of intermittent fever, contracted while he was living in a malarial region, but from this he made an excellent recovery. After this no definite illness occurred until March 2, 1885, when he was suddenly taken, while at work, with abdominal pain and vomiting. The former symptom was of short duration, but more or less irritability of stomach persisted until quite late in the evening, and on the following day, though somewhat better, he was still unable to work.

On March 4th, the patient, whom I now saw for the first time, was found to have a temperature of $101\frac{4}{5}°$, and a pulse of 92; he was notably weak, complained of pains in the extremities, and presented a marked expression of hebetude. His tongue, though moist, was heavily coated, and there was slight nausea, with tendency to loose bowels; the abdomen was somewhat full but not tender. There was cough from bronchial irritation, as shown by numerous coarse râles in the chest, but there was no dulness upon percussion in any part. The patient was ordered to have a liquid diet and to take quinine and a mineral acid.

On the 6th, the morning temperature was $102\frac{4}{5}°$, and the pulse 96; the bowels were still somewhat loose, and the abdomen was rather meteoric.

On the 14th, the note was taken that the patient was quite delirious at night, and though he was rational during the day, his hebetude was extreme, and he was excessively deaf, so much so, that he had to be spoken to in the loudest voice. The morning temperature was $102\frac{3}{5}°$, and in the evening it was 104°; the pulse was 104 in the morning and 116 in the evening. The patient had had epistaxis of moderate severity on several occasions. His cough was excessive but was not accompanied by expectoration. Physical examination revealed coarse mucous râles on both sides of the chest, and friction with impaired resonance at the right base. The tongue was heavily coated and dry, with tendency to browning in the centre. The abdomen was tympanitic, and upon its surface and upon the lower part of the chest there was a copious eruption of rose spots. The right hypochondrium was somewhat prominent, and on deep pressure there was marked tenderness of this region and of the epigastrium. The limit of absolute hepatic dulness began above the sixth rib and extended to a point below the costal border. The bowels, though confined, were exceedingly sensitive to the action of a laxative, a small teaspoonful of oil causing several thin, ochre-yellow stools. The

patient was ordered carbonate of ammonia and turpentine, with moderate stimulation in addition to his quinine, and was to have turpentine stupes applied to the chest, morning and evening.

On the 21st, the delirium at night was more pronounced, and there was occasional wandering during the day. The temperature range for the morning was from 102° to 103°, and for the evening 102⅘° to 104°; the pulse 100 to 120, was weaker and decidedly dicrotic. The cough, which was excessive, indeed, at times almost incessant, was attended with pain in the lower part of the right chest; the respirations were 36 and somewhat shallow. On the right side of the chest the dulness upon percussion began in the fourth interspace and extended beyond the border of the ribs; posteriorly on the same side the percussion note was dull from the spine of the scapula to the eighth rib, and absolutely flat from this point to the base of the chest. Above in the dull region there were lessened vocal fremitus, indistinct blowing respiration, and, on full inspiration, coarse friction. Spots were still to be seen on the abdomen and chest, but they were of a darker color and did not quite disappear on pressure. There was also a copious eruption of sudamina. Exhaustive sweats occurred daily, usually in the afternoon, leaving the patient in a state of intense prostration and calling for frequent stimulation.

On April 4th, the patient was rapidly losing flesh and appeared greatly exhausted. The pulse was exceedingly weak and there was more or less constant delirium. The tongue, tremulously protruded, was dry and brown; there was no vomiting; the bowels were quite loose again, but the frequency of the movements was under the control of small doses of opium. The abdominal symptoms were unchanged, excepting as regarded a recently developed sense of fluctuation over the right lobe of the liver, which removed all doubts, if there were any, of the existence of abscess. The cough, always dry, was still excessive and painful. The effusion in the right pleural cavity had increased, and the right lung, partly from this cause and partly from the encroachment of the enlarged liver, was pushed high up in the chest. The pain in the right side, frequently complained of, was in a measure relieved by the application of stupes.

On April 9th Dr. Hutchinson kindly examined the patient with me, more especially with a view of determining the propriety of attempting to remove the contents of the abscess by operation. On due consideration, however, a procedure of this kind was considered unjustifiable, because of the patient's low state, and because of the possibility of there being more than one abscess. The correctness of this decision, as will be seen further on, was verified by the results of the autopsy. From this time on, there was nothing especially interesting to note beyond the fact that the patient, kept alive by a retentive stomach, finally died from exhaustion on the 25th of April, the fifty-eighth day of his illness.

At the autopsy, made forty-eight hours after death, the body was found to be in a state of extreme emaciation. On opening the chest a large serous effusion was found on the right side, with patches of lymph scattered here and there on the costal and pulmonary pleura, and many easily torn adhesions.

The lung itself, though greatly compressed, was still capable of being inflated.

On the left side there was nothing especially abnormal beyond congestion of the bronchial mucous membrane, and marked emphysema of the borders of the lung.

There was no lesion of the heart.

The liver was found to be enormously enlarged, the anterior part of the right lobe being distended with thick creamy pus. Two smaller abscesses occupied the posterior border, between which and the larger one in front there was no discoverable communication. In the left lobe there was a single small collection of pus.

There were patches of recent lymph on the upper surface of the right lobe, and several adhesions of older date. The gall-bladder was normal in appearance, and there was no occlusion of any of the larger bile-ducts.

Examination of the small intestine revealed at the lower end of the ileum several patches of Peyer actively ulcerated, and others partly or wholly cicatrized.

Remarks.—The above case illustrates, judging from accounts heretofore published, a very rare complication of typhoid fever; indeed, after a search made as thorough as time would permit, I have succeeded in finding but two cases of the kind distinctly reported, both by Bueckling.

Greisinger mentions it as an occasional sequel of typhoid fever, but does not give cases, and Leudet states that cases have been observed by Louis, Andral, Barth, and Tardieu.

It seems to me, however, that in view of the well-known frequent occurrence of hepatic abscess with intestinal lesions of other diseases, particularly dysentery, that in connection with typhoid fever, a disease characterized by ulceration of the intestine, a like association may have been occasionally overlooked. Especially may this be true of localities where suppurative disease of the liver is not an uncommon disorder.

Excepting in hospitals, post-mortem examinations of typhoid fever cases are rarely, if ever, made, and in the former the condition of the liver is not always inquired into, the object of the autopsy being, as a rule, to expose the intestinal lesions for special study, or to satisfy a doubt as to the presence of perforation or other accident.

Without discussing the conflicting opinions held in regard to the pathological bearings of intestinal ulceration and hepatic abscess, it may be sufficient to state that the weight of authority inclines to the belief that in a large percentage of cases there is an intimate causal relation between the two, while, in other instances, the coexistence of the two conditions must be looked upon as purely accidental, the inflammation of the liver having actually antedated the intestinal disease.

Assuming the above view to be the correct one, it must be admitted that conditions favorable to the development of suppurative disease of the liver exist

in typhoid fever, and perhaps the attention I have drawn to the subject may be the means of calling out other reports.

In regard to the origin of this patient's illness no satisfactory explanation could be given, isolated cases of typhoid being of such rare occurrence in the country. Local outbreaks of fever, however, are far from being uncommon, even in the healthiest country district, but may always, I think, on careful investigation, be traced to their proper origin.

Such an epidemic occurred at Rosemont, on the line of the Pennsylvania Railway, last year, a brief sketch of which, in this connection, may be of some interest. According to my belief the disease originated by importation, the first case having been that of a lady, a patient of my own, who must have been actually ill with the disease at the time of her arrival at Rosemont. This belief is further strengthened by the fact that the patient had recently left a locality which was itself the scene of an outbreak of typhoid of virulent type.

The infection of a district previously healthy by the arrival in it of a person suffering from typhoid is an admitted fact, though Murchison states that "such occurrences are exceptional, and that the number of cases where the disease is introduced into a new locality without spreading, far exceeds that in which it is propagated."

In the case of the Rosemont epidemic I am sure that the disease would not have taken such a hold had its propagation not been favored by a well-known unsanitary condition of the immediate surroundings. Since this occurrence of fever, however, improvements have been made, and the lesson taught will be, I trust, a lasting one.

The case to which I have alluded as being responsible for this outbreak of fever proved so rapidly fatal, and bore such a striking resemblance to typhus, that a detailed report of it may be of interest:

Miss A., aged twenty-three, was taken ill while visiting a friend at Rosemont, on the night of June 13, 1885, having arrived from an adjoining State two days before seemingly in her usual health, which at the best of times was never good. When I was called to the patient on the 14th, I learned that she had had vomiting and diarrhœa during the night, but there was nothing to attract special attention beyond what might follow an acute gastro-intestinal attack. On the 15th, however, there was suspicious prostration, with increasing temperature, and an exceedingly feeble pulse. There were complaints of general articular pains, especially localized in the right knee, which joint was tender but not red or swollen. On the 16th the temperature was 103° in the morning and the pulse 116. There were evident hebetude and slight hesitation of speech, though no actual delirium. The tongue was red, and somewhat dry in the centre, the stomach exceedingly irritable, but retaining small quantities of milk and ammonia; the bowels inclined to looseness, and the abdomen full but not tender.

On the 17th vomiting better, and bowels not so loose; the tongue very red and irregularly coated, and there was slight tenderness in the right iliac fossa. There was delirium during the night. The patient's face was pale, the pupils dilated, and the skin hot and dry; temperature 104⅘°.

On the 18th, violent delirium during the night; there was marked subsultus and slight deafness; temperature 104°; pulse 120, and dicrotic; first sound of the heart almost inaudible; slight nose-bleed.

On the 20th, periods of delirium occurred more frequently; skin hot and dry, and covered with petechiæ.

On the 21st, more or less constant delirium and intense prostration; temperature 105°; pulse 120; tongue red as before, with dry centre; teeth covered with sordes; bowels moved several times daily; abdomen quite tympanitic; petechiæ more numerous.

On the 22d, patient violently delirious, requiring the combined efforts of two nurses and an assistant to keep her in bed; refuses all nourishment.

On the 23d, death occurred during the night, the patient having become comatose.

Between the date of this case and the early part of December following, there were forty-three persons attacked with fever in Rosemont, or within a radius of two miles of that locality. All of the cases occurring outside of Rosemont were related in some way to the source of infection, either by actual intercourse with the sick on the part of the individuals attacked or by having to do daily work there, Rosemont being a centre of several trades.

Out of the forty-three cases seven ended fatally. Intestinal hemorrhage occurred in eight cases, of which three were fatal. Infrequency of diarrhœa was the rule, and in many cases the eruption was either absent or imperfectly developed. In other respects there were no peculiarities worthy of note.

Ardmore, Pa., June 11, 1886.

HOMATROPIN HYDROBROMATE.

By EDWARD JACKSON, A.M., M.D.,
Chief of the Eye Clinic in the Philadelphia Polyclinic.

Its Value as a Mydriatic.

Homatropin is an efficient, reliable mydriatic. Still, many who are engaged in the practice of ophthalmology do not so regard it; and their idea that its mydriatic power is weak and uncertain, finds support in the literature pertaining to it. Such an impression is supported directly by the observations of those who have used the drug, and failed to get full mydriasis and paralysis of accommodation with it; and indirectly by the testimony of those who claim complete success with it, yet evince loose notions of what constitutes complete mydriasis, or who claim to have attained the desired result by methods of application that have frequently proven ineffectual in the hands of others. That is, there is not only direct testimony against the efficiency of homatropin, but, indirectly, some of the testimony in its favor is unreliable. To meet this it must be shown, first, that certain observers have not employed the drug in such a way as to develop its full power; second, that there is other testimony in its favor that cannot be impeached.

It is true of any mydriatic that when not applied

in sufficient quantity, when the applications have not been repeated often enough, or when too long a time or too short a time is suffered to elapse after its application, the accommodation is found incompletely paralyzed. And, as of other mydriatics, this is true of homatropin. It is also true that the dose of homatropin, and the time of its maximum effect, differ from the dose and the time for other mydriatics. Hence, to use homatropin as we use atropin or duboisin is unsatisfactory. It would, for different reasons, be even more unsatisfactory to use the latter drugs as homatropin should be used.

Strength of Solution.—I have always used homatropin as the hydrobromate, dissolved in distilled water. No material deterioration has been noticed after the solution has been kept several weeks, although, like other solutions of alkaloids, it becomes infested with low forms of vegetable life. Commencing with a solution of 1 in 80, I soon increased it to 1 in 60, and later to 1 in 50 (two per cent.). The latter or a two and a half per cent. solution (1 in 40) I have used habitually for the last four years, and still find it most satisfactory. I have also used three, four, five, and ten per cent. solutions, the latter being almost a saturated solution of the samples of the drug that have come to me. Solutions of 1 to 100, 1 to 200, 1 to 500, and 1 to 5000, have also been tried. The two or two and one-half per cent. solution is preferred, because weaker solutions sometimes fail to produce complete paralysis of accommodation at the usual time, and though a one per cent. or even a weaker solution will generally and if persistently applied, probably always, secure complete paralysis of accommodation, it is inconvenient to find some accommodative power present when the time comes at which it was intended to proceed to measure the refraction. On the other hand, the drug is too costly to be wasted, and stronger solutions cannot be relied on, unless used in the same way as that chosen above. For simply dilating the pupil a strength of 1 to 500, or a grain to an ounce, is commonly sufficient; and for purposes of diagnosis it should be relied on to the exclusion of stronger solutions, or those of atropin, duboisin, daturin, or hyoscyamin in all persons who, having passed the age of fifty, have lost most of the power of accommodation, and are liable to senile glaucoma.

Repeated instillations must be used where it is desired to secure complete paralysis of accommodation. Sometimes a single instillation of a one per cent. solution will accomplish it. But, on the other hand, I have more than once seen a full instillation of a ten per cent. solution fail to give it. Two or three instillations of the two per cent. solution will almost always secure it, and four or five thorough instillations of that solution will completely paralyze the accommodation in every case. At least, I have not yet found it fail to do so. This subject is further pursued under a different heading.

The instillations must be repeated at short intervals, to get the full mydriatic effect. Say from five to ten minutes apart. The safety of such a course will appear from what is to be said of its general action. The necessity for it arises from the brevity of the influence of the drug, and the importance of getting the effect of the whole amount used, at the time that it is desired to have the accommodative power completely in abeyance.

The mydriasis produced by homatropin, used as above indicated, closely resembles that produced by atropin, duboisin, daturin, or hyoscyamin, except that it is of shorter duration. Enlargement of the pupil and paresis of accommodation begin and end together. The shortest period between the first instillation and the first noticeable change in the pupil, was seven minutes, the longest was twenty-eight minutes. Usually it was between ten and twenty minutes. The shortest period between the last instillation and complete recovery was twenty-three hours; the longest, less than ninety-six hours. Patients have stated that they had entirely recovered in as little as twelve hours, but they did not return to have the fact verified; and I have often noted remaining mydriasis in those who thought it had passed off several hours, or even a day before. On the other hand, with homatropin, as with other mydriatics, an occasional patient will continue to ascribe symptoms to the mydriatic after its effect has really passed away. The drug attains complete control of accommodation in from forty to ninety minutes after the first instillation, usually at the end of the first hour; and used according to the method above indicated, this complete control of accommodation is retained for a period of from one to six hours without further instillations. By careful instillations repeated every hour, it may be sustained indefinitely. To determine the state of refraction in young persons, the second hour after completing the cumulative instillations is the best time.

Its reliability as a mydriatic is absolute if the drug be properly used. From the brevity of its action and its cost, it is especially important that each instillation be effectually made. When other mydriatics are used, such as duboisin, the eye at any one time will feel the effect of all the instillations that have been made in the preceding three or four days. And if one or several of these have been ineffectual, the others will often be sufficient to produce the desired effect. But this would not be true of homatropin, unless the strong solution were being instilled at intervals of a half hour or less. When the instillation of the drug is entrusted to a person entirely inexperienced in such a manipulation, it is almost certain that some of the instillations will be ineffectual, and that much less of the drug will find its way into the eye than the number of instillations would lead one to suppose. This is the explanation of some cases of apparent obstinate resistance to the action of a mydriatic. Hence, I commonly instill homatropin myself. I did so in all the cases, two hundred and eighty, used as the basis of this paper.

It is not perfectly easy to determine when the power of accommodation is in complete abeyance. Only careful and somewhat prolonged testing will make this certain. To decide the point I have used three tests: First, is there complete inability to vary the distance at which fine print can be read through convex glasses? Second, do weak (quarter or half dioptric) convex and concave lenses, added to the correcting lens, equally impair distant vision?

No.	Age.	Correction under Homatropin.	Correction under second Mydriatic.

Third, *is there no tendency to increased refractive power (lower H., higher M.) after prolonged subjective tests in a good light?* The first I employed in the earlier cases, but have found not entirely satisfactory, because I could not get fine print of the right size and clearness. And there is also the objection that letters seen at a variable distance should be of a variable size. The others have been used in all cases, the third being regarded as most conclusive. I cannot claim that, in all cases in which I have used homatropin I had absolute paralysis of accommodation. All I claim is that a two per cent., or stronger, solution, used in the way proper to it, paralyzes the accommodation just as certainly and thoroughly as a one per cent. solution of atropin or a one-half per cent. solution of duboisin used in the most effective manner. The relative value of homatropin is well shown by the accompanying table. This includes, first, all those cases occurring in private practice, where, after using homatropin and getting a certain result, I so far distrusted the result as to follow with some other mydriatic of better established reputation. Second, some cases from the service of Dr. George C. Harlan, at the Pennsylvania Hospital, in which homatropin was employed for the purpose of testing its relative value. These latter cases were picked in so far as to exclude all too ignorant to allow of satisfactory subjective testing, or whose vision could not be brought to the normal standard by the correction of the ametropia.

Those of the first class often failed to get normal vision with their correcting glasses, such failure being usually associated with high degrees of ametropia. The second column gives the ages of the patients; the third, the correcting lenses selected under homatropin and the vision obtained with them; the fourth, the correcting lenses selected under the other mydriatic and the vision obtained with them.

In all these cases the use of the second mydriatic was begun while the eye was yet under the influence of homatropin, and was continued for from one to seven days before the state of refraction was again tested. In the cases numbered 1, 3, 4, 6, 13, 20, and 24, the second mydriatic was atropin. In cases 2, 11, 13, and 17, it was daturin. In cases 5, 7, 8, 9, 10, 11, 12, 13, 14, 15, 16, 17, 18, 19, 20, 22, 23, 24, and 26, it was duboisin. Case 13 was subjected successively to homatropin, daturin, duboisin, and atropin. The homatropin was always instilled by myself, the second mydriatic commonly used at the patient's home.

Extended analysis of the table is unnecessary; it need only be remarked that in but fifteen out of the fifty-two eyes was there any difference between the first and second results. In eight of these it was one-quarter dioptric in favor of the second mydriatic, in five it was one-quarter dioptric in favor of homatropin, in one it was (in one meridian) one-half dioptric in favor of homatropin, and in another the same in favor of duboisin. In no case was the variation greater than may well be allowed for unavoidable inaccuracy of observation. In no case was the apparent axis of the astigmatism materially changed. When it is borne in mind that the majority of these cases were subjected to the second mydriatic because I was, more than in most cases, inclined to distrust the completeness of the paralysis produced by homatropin, the thorough reliability of homatropin (properly used) as an aid in the diagnosis of ametropia, seems to me incontestable.

Certainly cases such as the above constitute testimony more competent than may be drawn from those in which considerable time has elapsed after the use of the one mydriatic before the second is resorted to. For well-tested cases have convinced me that the state of refraction may change considerably even in a few months, not only toward increased M. and diminished H. but also in the opposite direction. As such cases have already been recorded by others, none need be introduced here.

The General Action of Homatropin.

Solutions of homatropin of ordinary strength produce little if any more unpleasant sensation when applied to the conjunctiva than does distilled water. Five and ten per cent. solutions, especially the latter, cause a notable smarting. This has not, however, in any case lasted as much as five minutes. On other mucous membranes no such sensation is produced. I have never had an opportunity of seeing a conjunctivitis induced or aggravated by the use of any mydriatic. Most writers on this subject mention the occurrence of "conjunctival irritation" after the use of homatropin. The phenomenon referred to very generally attends the instillation of the drug; but I certainly cannot regard it as a conjunctival irritation. It is something entirely different from what occurs after an irritant is applied to the conjunctiva.

When sulphate of copper, mitigated nitrate of silver, or solution of nitrate of silver or sulphate of zinc, of the strengths ordinarily used in ophthalmic practice, glycerole of tannin, boroglyceride, or any decidedly acid solution, is applied to the normal conjunctiva, there is, instantly, a decided sense of smarting, and very quickly marked enlargement of the conjunctival vessels, the smarting and hyperæmia being rather proportioned the one to the other. As the smarting subsides, the hyperæmia subsides; and when all abnormal sensation has disappeared the conjunctival vessels will have returned to pretty nearly their original condition. In contrast with this, let us consider what occurs after the instillation of homatropin. Generally, after the use of a solution as strong as one per cent., nearly always after the cumulative use of a two per cent. solution, and invariably, so far as I have observed, after introducing the ten per cent. solution this occurs: The smarting, if it amounts to that, caused by the instillation, quickly subsides, the appearance of the conjunctiva remaining normal; but after three, five, or ten minutes the normal whiteness of the sclerotic is interrupted by an increased vascularity. This becomes more and more marked, reaches its height about the time the pupil has fairly begun to dilate, remains for a little while stationary, then gradually subsides; so that by the time the mydriatic effect of the drug has reached or just passed the maximum, unless the instillations have been continued, the appearance of the sclerotic has again become normal. This process is entirely unattended by smarting, or any other sensation to be connected with it. The vessels of the palpebral conjunctiva are not noticeably involved. Those of the ocular conjunctiva are somewhat dilated, but the *reddening of the eye is mainly due to the enlargement of the minute vessels that form a rosy zone around the cornea, the straight vessels, and the deeper vessels of the sclerotic.* This hyperæmia is not due to the distilled water which has been used to convey the homatropin to the tissues; for distilled water alone does not produce the least hyperæmia in the normal eye. It is not due to acidity of the solution, for the hyperæmia from that cause is entirely different both in time of appearance and in the non-involvement of the deeper vessels. Moreover, the very slight acidity of the preparations I have used was never sufficient to cause hyperæmia, well-prepared litmus paper being a much more delicate test for acids than increased vascularity of the conjunctiva. I believe this hyperæmia to be due to a specific influence of the drug on those vessels through which, in comparatively concentrated solution, it makes its way to the general circulation.

This effect is not, however, peculiar to homatropin, the same thing occurs after instillations of atropin, duboisin, and daturin, and doubtless, though this I have not tested, after hyoscyamin. That it

should not have been observed with reference to these latter, is to be accounted for by the fact that two per cent. solutions of them, or solutions approaching that strength, are not often used in normal eyes. It is not necessary to comment here upon the influence these observations may have upon theories of the action of mydriatics in ocular inflammations.

Placed on the tongue, homatropin causes a decided bitter taste, which, with strong solutions, lasts for some ten minutes or longer. This taste is very generally noticed by the patient when the drug is at all freely applied in the conjunctival sac. It is then doubtless caused by the portion which makes its way through the lachrymal passages to the mouth. That homatropin produces no dryness or irritation of the mouth or throat, is confirmed by my experience. Very often the direct question was asked, Was any sensation of the kind experienced? In every case but one it was answered negatively. In the exceptional case the patient had previously used atropin, and hastened to say that it was entirely different from the sensations produced by that drug, and of his own accord offered the supposition that the feeling he had experienced was probably not due to the homatropin, but to other causes.

The *local effects produced by the hypodermatic injection of homatropin* are of especial interest when considered in connection with the hyperæmia it produces in the eye. For purposes of comparison, it may be well to bear in mind that the hypodermatic injection of distilled water causes slight smarting in the tract of the wound, and if the injection is large and rapidly thrown in, there may be a sharp pain felt at the point of puncture; which disappears, as pressure is removed from the piston, to return when the fluid is again urged forward, but ceases finally within a minute or two after the completion of the injection. Dependent on the situation and size of the injection, there may be some aching in the part. This lasts but a few minutes. There may also be some numbness, which, in one case, the injection being some twenty minims and placed near the course of the ulnar nerve, extended from the elbow to the tips of the little and ring fingers. But these symptoms all disappear within an hour, leaving only a minute red point to mark the seat of injection; and this, too, has usually disappeared two or three days later. The local effects of a solution of homatropin applied in the same way, are best shown by the following account transcribed from the record of an experiment:

Experiment.—Subject, male, aged twenty-nine. Five minims of a two and one-half per cent. solution, equal to one-eighth grain of the drug, were thrown into the subcutaneous cellular tissue on the outer aspect of the forearm at its upper third. The discomfort was not greater than that produced by distilled water.

15 minutes. There is a distinct elevation of the surface several millimetres in diameter like a wheal, with a pale centre and reddened margins.

25 minutes. This wheal is getting redder in the centre and its red margin is extending outward. It is becoming less elevated.

40 minutes. There is now a reddened area about forty millimetres in diameter. There has been no noticeable impairment or exaltation of sensibility to touch, pain, or heat and cold in this area.

60 minutes. The local redness is fading markedly.

90 minutes. The local redness has almost entirely disappeared: being confined to the immediate neighborhood of the puncture and shading imperceptibly away into the normal color of the skin around it.

10 hours (the next morning). The point of injection is now surrounded by a distinct pink areola some fifty millimetres in diameter, quite tender to the touch.

14 hours. The areola is very distinct, quite red with a sharply marked edge (to the coloring, there is no appreciable swelling), very tender but not altered in size.

36 hours. Areola fading, though still distinct and sore to touch.

Third day. Areola much the same. There is distinct swelling about the point of puncture.

Fourth day. Areola fainter but still perceptibly pink and tender. Its margin not so well defined.

Fifth day. Areola about gone. There is now a distinct, increasing, conoidal, indurated swelling about the seat of puncture, reddened at the apex and sore on pressure.

Sixteenth day. This swelling is now some thirty millimetres in diameter, quite sore and softening at the centre.

Thirty-seventh day. The swelling has somewhat subsided; the softened portion is some twenty millimetres in diameter, covered with purple insensitive skin and surrounded by a narrow ring of induration.

Repetitions of this experiment resulted in essentially the same train of symptoms. The protuberance arising a few minutes after the injection was irregularly flat with abrupt edges, differing entirely from the rounded swelling produced by the subcutaneous injection of fluid; and much wider than the minute elevation that commonly arises at the point of puncture. It was always comparatively pale, sometimes appearing absolutely bloodless; but with a hyperæmic margin which encroached upon it after a little time, and presently swallowed it up. In its turn this primary redness disappeared except at the seat of puncture, to be succeeded some hours later by a larger and more lasting area of hyperæmia. But even the secondary hyperæmia seemed to have no connection with the later inflammation and abscess. The primary hyperæmia seems to me strictly comparable with that noticed in the eye. The late swelling and abscess may be accounted for as eliminative of tissue killed, or hopelessly damaged by contact with a concentrated solution of the drug. That it was not due to accidental contamination of the syringe or fluid injected, is indicated by the facts that the syringe was washed out with boiling water, and the solution boiled immediately before the injection; and that distilled water injected through the same needle with the same syringe, into the same arm, at the same time, failed to produce any unusual effects. Abscess was repeatedly produced, it only followed the injection of at least one-tenth of a grain of the drug in strong (two and one-half per cent) solution. Injection of a smaller amount of the drug or the same amount but in more dilute solution failed to cause anything of the kind. The wheal-like elevation about the seat of puncture was always noticed, as was the primary reddening of the neighboring surface, the extent and duration of these symptoms being directly proportioned to

the dose. The secondary hyperæmia and accompanying tenderness are also directly proportioned to the dose, but were not noticed when less than one-hundredth of a grain had been introduced. The soreness to light touch generally outlasted any noticeable discoloration of the skin.

Action upon the Nervous System.—When a two per cent. solution is used so as to get its cumulative effect on both eyes at once, the total amount of the drug placed in the two conjunctival sacs may be as much as one-eighth to one-fourth of a grain. When using the drug in this way I have nearly always made special inquiry for symptoms referable to it, and have almost invariably elicited negative replies. The same absence of subjective symptoms attended the taking of one-eighth or one-sixth of a grain on the empty stomach. In three instances, however, after pretty liberal use of the drug in both eyes, patients spoke of feeling a little "strange" or "intoxicated;" but neither their speech nor movements gave any objective evidence of such a condition, and I was inclined to attach no importance to their statements, opposed as they were to those of a great majority of the persons subjected to such influence, until the following occurrence convinced me that it was not unlikely that such statements were accurate. By a mistake as to the graduation of a hypodermatic syringe, I received fully one-fourth of a grain of homatropin in the subcutaneous tissue of the forearm.

Experiment.—This occurred at 8.45 P. M., supper had been eaten at 7 P. M., and my pulse was at the time 64 while sitting, and 72 when standing. Power of accommodation = 9 dioptrics, pupils, facing the full light of an argand burner, 3 mm. in diameter.

8.50 no change.

8.55 pulse 60 and stronger.

9.00 pulse 66, a very decided sense of intoxication.

9.03 pupils 4 mm. in diameter, facing the light as before.

9.05 pulse 68.

9.10 the power of accommodation is so impaired that it is impossible to see clearly anything within twelve inches of the eye. Convergence of the visual axes for any point within that distance is also impossible. There is also a sense of difficulty in making any coördinated ocular movements, although no diplopia is noticed. Pupils 4 mm. in diameter.

9.15 pulse 64, fuller than before taking the drug.

9.25 pulse 66, the same sense of intoxication, pupils, and power of accommodation and convergence as at 9.10.

9.35 and 9.45 pulse 66.

9.55 pulse 64, sense of intoxication and difficulty of accommodation and convergence slightly diminished.

10.05 pulse 60, pupils smaller.

10.15 pulse 62. Going out of doors there is some little difficulty in walking, a distinct tendency to drag the toes. Recovery now proceeded rapidly.

11.15 pulse 58, pupils, accommodation, and ocular movements, normal; a very slight headache.

The intoxication much resembled that produced by alcohol. It was peculiar in that there was a sense of great delay in the succession of ideas. There was no feeling of depression, rather of comfort, satisfaction, and indisposition to exertion.

The effects upon the pupil and accommodation were so transient, when compared with the same effects produced by a local application of the drug, and the dilatation of the pupil was so insignificant, as compared with the impairment of accommodation, that I cannot regard them as due to any local action of the drug reaching the eye through the circulation, but rather with the interference with the action of other ocular muscles, as due to the influence of the drug upon special parts of the central nervous system.

By other experiments I have found that the one-eighth of a grain of homatropin taken hypodermatically always causes some little intoxication. Once, when taken fasting, it seemed to cause about as much as the fourth of a grain, above mentioned, except that the influence it exerted over ocular movements was much less.

Influence upon the Circulation.—Ringer found, with reference to the action of the heart, that "homatropin slows the beats and renders them irregular in force and rhythm." In my experience a decrease in the pulse-rate is the most constant symptom produced. Next to this is an increase in the fulness and force of the radial pulse. In but three out of seventy cases was there any certain disturbance of rhythm. In two of these there was some irregularity of rhythm to start with, which became much more marked after the use of the drug. In the third, irregularity of action was noticed only after the employment of this drug. The increase in the force is noticeable, mainly within thirty to sixty minutes after the application of the homatropin.

Later there is a certain diminution of force, but that the pulsations become weaker than before the drug was taken I think is very uncommon. I could not satisfy myself that it occurred in any case. In one patient with mitral regurgitation, but fair circulation, homatropin seemed to cause a marked improvement in the strength of the pulse, which improvement lasted some hours. The preceding table shows the effect on pulse-rate produced by the use of the drug for its mydriatic effect. In the successive columns are found the estimated amount of the drug employed (by cumulative instillations), the ages, sex, normal pulse-rate under homatropin, and the difference produced by the drug.

The dose is expressed in fractions of a grain, the pulse-rate, of course, by the number of beats per minute. The observations were all made when the subject was in the sitting posture, free from excitement, and when time had elapsed since any considerable exertion. A cursory glance at the table shows that the slowing of the pulse is of pretty constant occurrence; yet it is probably even more constant than the table would indicate. In these cases it was not practicable to watch the pulse constantly, or at frequent intervals throughout the time that the influence of the drug was manifest. The normal pulse-rate was determined before the use of the drug and after recovery, but often the observations on the pulse-rate produced by the drug, were confined to the period at which the mydriatic influence was most complete, the patient being the remainder of the time from under observation. Now upon looking at the account of the experiment in which I received one-fourth of a grain, it well be noticed that the pulse first fell to sixty, then quickly rose to sixty-eight, after an hour fell again, and at two hours it was fifty-eight. A similar fall, rise, and second fall were noted after the use of one-eighth or one-tenth of a grain. Also in patients who had such amounts placed in the conjunctival sac, and who remained under observation until all effects of the drug had passed off. So it is likely, if not certain, that some of the patients referred to above, who seemed to have the pulse-rate but little if at all affected, were seen only during the period of such a secondary rise. It will also appear from the table, and from what has just been said, that the influence upon the pulse-rate is not proportional to the dose. While large doses slow the pulse both early and late, they do not slow it more than a dose so small as not to produce secondary rise. The secondary quickening of the pulse seems to be connected with the intoxication produced by the drug. This was pointed out to me by Dr. Thos. J. Mays, to whom my thanks are due for assistance in testing the action of the drug when applied hypodermatically.

Summary. — Homatropin applied in sufficient quantity by cumulative instillation is a perfectly reliable mydriatic in all cases. Locally, it causes hyperæmia, and affects nutrition, when in concentrated solution, so profoundly as to cause tissue death. In ordinary doses ($\frac{1}{200}$ to $\frac{1}{20}$ of a grain) it slows the pulse, makes it fuller and perhaps irregular in rhythm. In large doses ($\frac{1}{8}$ of a grain and upward) administered hypodermatically it causes intoxication.

The really valuable literature of the subject is comprised in the following papers:

Tweedy and Ringer. On the Mydriatic Properties of Homatropia or Oxtoluyltropein, with an account of its General Physiological Action. *Lancet*, 1880, vol. i. p. 795.

HOSPITAL NOTES.

NOTES FROM THE VIENNA CLINICS.

(Reported by E. P. Davis, M.D.)

CARL BRAUN'S TREATMENT OF PUERPERAL SEPSIS.

Prof. Carl Braun has recently adopted a mode of treatment in cases of puerperal sepsis which has generally proved most efficient. As soon as a marked rise in temperature occurs the interior of the uterus is thoroughly curetted and disinfected by an antiseptic fluid, usually thymol. The curettte removes masses of decidua, blood-clots, and often pieces of membrane the presence of which would not be suspected, as the labor may have been normal. To be efficient, the operation must be done thoroughly yet gently, and, when so performed the temperature has often fallen several degrees and in a short time become normal, and a normal lying-in period ensued. An iodoform pencil or uterine suppository is often placed in the cervix after the operation, and antiseptic gauze in the vagina to absorb discharges.

ACTINOMYX IN THE PERITONEAL CAVITY.

During the past six weeks the clinic of Prof. Nothnagel has, as usual, presented much of interest.

The actinomyx is well known to American and European surgeons, but it has been, as yet, very rarely observed in the peritoneal cavity.

The case in question was that of a young man who had suffered from a circumscribed peritonitis, which had resulted in a fistula on the right side of the navel. The clear fluid and kernel-like masses which accompany actinomyx were present, and the microscope made the diagnosis easy and plain. The actinomyx had been undoubtedly taken with food, an intestinal obstruction had caused a perityphlitis—at least a circumscribed peritonitis—and a fistula resulted. The fistulous tract was operated on by Prof. Billroth.

ADDISON'S DISEASE.

Two interesting cases of Addison's disease were also presented, and tuberculosis of the suprarenal capsules adduced as the cause.

A SERIES OF CASES OF SPLENIC TUMOR.

A series of cases of splenic tumor were observed, leukynia in varying forms and carcinoma being the

causes of these tumors. There was also a series of cases of hæmatemesis, in which ulcer of the stomach and varices of the œsophagus (in a case of hypertrophic liver cirrhosis) were the pathological conditions present.

THE DIAGNOSIS OF PERNICIOUS OXALURIA.

The diagnosis of pernicious oxaluria was illustrated by a case in which the anchylostonum duodenalis was suspected but not found, as the cause of the disease.

CALOMEL AS A DIURETIC.

The use of calomel as a diuretic, which has already been tried in other clinics, has given, in some cases, interesting results here. It is efficacious only when the kidneys are healthy. In some cases of heart disease, in which as yet no interstitial changes had occurred, calomel produced free diuresis where other means had failed. It was given in rather large doses, and salivation rarely followed. No explanation is given of its mode of action.

MEDICAL PROGRESS.

SUGAR AND CORROSIVE SUBLIMATE AS A FIRST DRESSING IN WAR.—Dr. Heidenreich, in a paper published in the *Vrach* (Nos. 10 and 20), strongly recommends as a first dressing on the field of battle a mixture of corrosive sublimate with powdered sugar in the proportion of 1 to 1000. It is important that when this is prepared the sublimate should be evenly distributed, and this is easily effected by first dissolving the mercurial salt in a little spirit and then carefully rubbing up the sugar with it. The spirit ultimately evaporates and leaves a powdered mass of uniform composition. A little packet is supplied to each soldier containing a capsule in which are five grammes of the mixed powder—*i. e.*, $\frac{1}{200}$ of a gramme of sublimate—for the purpose of sprinkling on the wound; also a good-sized piece of gauze impregnated with one-third per cent. of its own weight of sublimate by means of Bergmann's process, which consists of dipping it in a solution containing 10 parts of sublimate to 500 of glycerine, 1000 of alcohol, and 1500 of water. Some hygroscopic wadding is also supplied, and this, when enclosed between two folds of the gauze, forms a dressing measuring 650 square centimetres, which is large enough to cover a somewhat extensive wound. The whole is enclosed by means of a layer of varnished paper and a triangle bandage, which is fastened with two safety pins. The author claims for this mixture of sugar and sublimate the advantage of being a particularly powerful antiseptic and quite innocuous. Sugar, he says, is the best substance for diluting the sublimate, being itself somewhat antiseptic. This dressing has also the additional advantage of being suitable for use wherever water may be procurable. This, of course, is not always the case, and where it is the source is frequently in a marsh or pool of anything but hygienic appearance. Under these circumstances, he advises that filtration should be resorted to, and consequently proposes that a kind of filter consisting of flannel impregnated with sublimate should be included in the packets supplied to the men. The whole contents of the packet weigh only seventy-five grammes, and are exceedingly portable and inexpensive.

PURE TEREBENE IN WINTER-COUGH.—J. HUTCHISON, M.D., of Shawlands, Glasgow, writes as follows to *The British Medical Journal*, of July 3, 1886: For some months past I have been using pure terebene in the treatment of winter-cough and bronchitis. I have before me notes of fifty-one cases so treated, and the conclusions at which I have arrived from my experience of the drug are as follows:

In cases where the trouble has not been of long standing, and the symptoms are slight cough, more especially at night; expectoration moderate in quantity and easily voided; no feeling of rawness in the chest, and little or no disturbance of the general health, I consider that pure terebene is almost to be ranked as a specific, so quickly is a cure effected.

In cases where there is emphysema, and the ailment has been present for some time, it may be for some years, with the following symptoms: cough very troublesome, and sometimes even violent; expectoration tough and adhesive, or it may be easy and copious; great shortness of breath and rawness of chest; sleep broken, and general health much disturbed, the beneficial effects of the medicine do not manifest themselves for some little time, and not unfrequently the dose has to be increased to ten, or even fifteen, drops. If, however, the drug be persevered with faithfully and regularly, the cases are few in which I have to record a failure. Altogether, I consider pure terebene one of the most valuable remedies at our command in the above class of cases.

In six cases of phthisis in which I prescribed the drug, the patients, in every instance but one, remarked that they were not in any way benefited, and requested the medicine to be changed. In catarrh, also, the results were not satisfactory.

My method of prescribing the drug was sometimes pure terebene alone—ten drops on sugar three times a day. In other cases I combined it with cod-liver oil, as follows: pure terebene, two drachms; cod-liver oil, to four ounces; two drachms three times daily. I cannot say, however, that the effects produced were any better in the one case than the other. If there were any difference, pure terebene alone had the preference.

Some of the patients complained that the medicine made them sick; others that their appetite was improved by it. In a few of the cases it appeared to have a laxative effect. In a very large proportion drowsiness was complained of; while in some giddiness, or even a slight transient intoxication, was observed.

TESTS FOR ALBUMEN IN URINE.—The "Albumen Test Committee" recently presented to the Clinical Society of London a paper on the work accomplished by them, which, according to custom, was received without discussion. In it, the Committee briefly reviewed the various modes of testing for urinary albumen, etc., in common use, and compared in turn Dr. Oliver's test-papers, Dr. Johnson's picric acid method, the potassio-mercuric iodide and acid, Dr. Pavy's pellets, the acid brine method, picric acid and brine, the acetic acid, and the nitric acid methods. After careful consideration and experiment, the Committee arrived at the conclusion that the papers of Dr. Oliver possessed advantages in the way of portability and delicacy of reaction over the other similar preparations; but,

apart from the question of easy carriage and compactness, they described nitric acid as being most reliable and delicate. All the methods, however, were said to be respectively useful for the determination of different proteids in the urine.

Tonsillar Orchitis and Ovaritis.—In an elaborate study, thus entitled, in the *Archives Générales de Médecine*, for May and June, 1886, M. Joal presents the following conclusions:

1. Orchitis and ovaritis should be classed among the complications of acute tonsillitis, either superficial or deep.

2. These genital manifestations, analogous to those which appear in typhoid fever and in *fievre ourleuse*, should be attributed to the infectious nature of the tonsillar inflammation.

3. The orchitis and ovaritis are not due to any of the alleged physiological nexuses, imagined by certain observers as existing between the generative organs and the tonsils.

Hemirheumatism.—At a recent meeting of the Academy of Medicine of Paris there was presented, for Dr. Cazalis, a note on the hemilateral predominance of the manifestations of chronic rheumatism. According to the author, a tendency to unilateral rheumatism is noted in two-thirds of such cases, the right side being most frequently affected. When pulmonary congestions, or bronchitis of arthritic nature appear in these patients, they are most often located on the side on which the rheumatism predominates. On this side, also, are most frequently found deviation and deformity of the great toe. If hemicrania be added to the various modalities of arthritism, there will be found still greater ground for admitting that the central system exerts a great influence in the localization of chronic manifestations.—*Archives Générales de Médecine*, June, 1886.

Epidemic Cerebro-spinal Meningitis.—In two consecutive numbers of the *Eira*, Dr. A. P. Silverskiold gives an interesting account of his observations on fifty-eight cases of cerebro-spinal meningitis during the Gothenburg epidemic of 1883. He adds a table of the relative frequency of these epidemics in different countries, which shows that Switzerland has had the greatest number, namely, fifty-eight; North America, sixteen; Sweden, seven; England and Italy, five each; Denmark, four; Spain and the Netherlands, only one each. The disease appears to rage during the winter and spring months. The Gothenburg epidemic commenced in January, reached its maximum in February and March, its minimum being in May and June. The disease commenced with a severe rigor, lasting from half an hour to six hours, followed by intense heat and headache. The rigors recurred at irregular intervals, and did not resemble those of pure ague. Unconsciousness and delirium usually set in quickly, in some cases coma, not always terminating fatally, even when the patient was perfectly livid. The temperature was not raised to any very abnormal extent, and some cases ended fatally with a temperature of only 40° C. (104° F.). All sorts of nervous symptoms were met with as complications, the prominent features being intense headache and pain in the back, shivering, convulsions, and delirium. Sometimes hydrocephalus occurred. During convalescence there were great changes in temperature which sometimes rose to 40° C., and sometimes fell to normal. Difficulty of swallowing and great distaste to food lasted during the whole period. The pulse was as irregular as the temperature; in most cases there was a slight increase in frequency. Dr. Silverskiöld tried a large number of drugs, without any satisfactory result. Salicine and quinine had scarcely any effect. Cold on the head and along the spine lessened the pain, but the most serviceable means were local bleeding and opiates. He found large doses of morphine most efficient in giving sleep when there were delirium and convulsions. Chloral was less frequently used, and opium was wholly avoided. When the most serious symptoms had abated, Dr. Silverskiöld used bromide of potassium to promote reabsorption. He is of opinion that the disease arises from malaria, and states at some length the ground for his belief, founded on observation of the physical features of the districts around Gothenburg, which are low and marshy. During an east wind these marshes are exposed, and exhale malarial vapors. In 1883, this was especially the case.—*Brit. Med. Journ.*, July 3, 1886.

Chemical Constitution and Physiological Action of Drugs.—At a recent meeting of the Cambridge Physiological Society Dr. J. Blake made some remarks on the discordant results that had been arrived at by different observers in investigating the connection between chemical constitution and physiological action. Brunton and Cash, in a paper published in the last volume of the *Trans. of the R. S.*, had concluded that no such connection could be shown; whilst Richet, Ringer, and Bothrin had arrived at the conclusion that such a connection existed when the chemical constitution of the elements was considered in relation to Mendelejeff's law. He (Dr. Blake) had published forty-five years ago, in a paper read before the Royal Society, what he considered was the relation between chemical constitution and physiological action, viz., that substances in the same isomorphous group exert analogous physiological action when introduced directly into the veins or arteries, and a larger number of experiments made with compounds of more than forty of the elements, had, he believed, fully established the truth of the connection of physiological action with isomorphism. The experiments which were performed by Brunton and Cash were not calculated to throw any light on the subject, as the reagents they employed were principally substances of the chemical constitution of which little is known, and the method they used, that of subcutaneous injection, introduces so many unknown factors that the results are comparatively worthless. By employing the same method Richet considered not only that he had proved the connection between physiological action and chemical constitution, but that he could even calculate a *toxicological constant* as a function of the atomic weight. Both in these experiments of Richet and in those of Bothrin their authors have been led into error by mistaking the arrest of the circulation caused by obstruction in the pulmonary arteries, as is the case with the salts of lithium, rubidium, and cæsium, with that caused by the paralysis of the heart that follows the injection of the salts of potash into the veins.

In answer to a question, Dr. Blake observed that isomorphism, although founded principally on the form

assumed by the crystalline compounds of an element, yet connoted a great deal more than mere resemblance in crystalline form, isomorphous elements resembling each other in many of their more marked chemical functions.—*The Journal of Physiology*, June, 1886.

Pulmonary Resection and Nephrectomy.—At a recent meeting of the *Société de Chirurgie*, M. Demons, of Bordeaux, narrated the case of an individual in whom a stab wound in the inferior portion of the thorax had determined a pulmonary hernia and a wound of the kidney. The protruding portion of the lung was resected, but several days later a fluid, shown by chemical analysis to be urine, was observed to pass out from the uncicatrized wound. In view of this urinary fistula, M. Demons performed nephrectomy, resulting in perfect cure.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, June 11, 1866.

Aphasia after Injury to the Head, the Faculty of Counting being Retained.—Dr. Volland, Davos-Dörfli (*Münchener medicinische Wochenschrift*, January 26, 1886) records the following case: A youth, aged fifteen, suffered a fall down a staircase into a cellar, where he was found in a state of insensibility. The actual height that he had fallen was not known, as no one else was present at the time of the accident. A moderately sized and sharp punctured wound was found on the right parietal bone, near the surface; the periosteum was detached to the extent of a line. The bone itself appeared uninjured, and no bleeding from the nose or ears occurred. The injury was treated as an open wound. The patient continued insensible the whole of the following day, and could not be made to take food. On the 16th he took nourishment and came to himself. No paralysis of extremities or of the face was present, but his friends stated that, although he understood what was said to him, he could make no reply. The only word he could utter was *Anna*, slowly articulated, in reply to his friends, and especially when he saw any object that pleased him; it was out of his power, by any effort, to get out any other word. The trial of writing was made, but it was exactly the same as with his speaking: the word *Anna* was illegibly scribbled. On the following day it was said that the patient could count, and at my request he, without hesitation, counted to 100. Furthermore, he could write down and count correctly any sum that he had previously learnt. For fourteen days that he lay ill, the difficulty of speech remained. As he recovered and the wound healed, he concurrently and gradually recovered speech and facility of writing. Six years afterward, when he had attained the age for military service, he still experienced difficulty of speech, and was subject to vertigo; had a sense of pressure on his head distinct from headache, and was the subject of ptosis. He was able, however, to follow his work as an agricultural laborer. The point of interest in this case, Dr. Volland observes, is that it seems to point to a centre for counting and expression of figures.—*Provincial Medical Journal*, July 1, 1886.

Treatment of Stammering.—In the *Bulletin de l'Academie Royale de Medicine de Belgique* for January, 1886, Dr. Chervin, of Paris, has an interesting article on the etiology and treatment of stammering. His treatment lasts only three weeks.

The *first week* is devoted to the study of the elements of speech, and to the methodic exercise of respiration, The respiratory rhythm must be established at the outset, and the patient must be taught to breathe and utilize his breath with a view to speaking. There are certain exercises of respiration, in which he teaches the subject how to inspire and how to expire, these acts being preceded by a moment of repose, during which the mouth is kept closed. Expiration is at first utilized in pronouncing the separate sounds, then combined sounds. The vowels are first chosen in the exercises, as they are easier to pronounce than the consonants. These latter are taken up and each carefully studied. When the elements of speech have been perfectly studied, and the difficulties arising in connection with individual consonants have been overcome by special gymnastic exercises, the subject passes to the study of syllables, then words, and, finally, sentences and paragraphs. During the first week the stammerer should abruptly break with his old manner of speaking. Dr. Chervin considers as a powerful aid in this work complete, absolute silence, which he imposes upon his patients during the first week. It is evident that as long as the principles of the method are not sufficiently known to the pupil, and he is not completely broken into their practice, he will not apply them in conversation. This rigorous silence has another effect. It quiets the pupil's mind, and makes him forget all about his stammering.

The *second week* the pupil regains freedom to speak. The time has arrived for him to apply the principles he has learned. Henceforward he can speak, because he no longer stammers; he restrains himself, and slowly puts into practice the instructions concerning respiration, the regular movements of the tongue and lips, etc.

It is always a surprise to Chervin to see the contortions, the spasms, the hesitations, the most marked repetitions, disappear under this method as if by enchantment. A clear, precise utterance succeeds the former stuttering; speaking will become natural, agreeable and harmonious, when the extreme methodic slowness imposed during the second week will have given way to an easier gait which is to be practised during the last week of the treatment.

The *third week* is employed in fixing the new habit of speaking with care and method, and in relieving the delivery of all tendency to choking. At the same time a careful study is made of the inflections of the voice.

In fine, Chervin replaces the very marked syllabation of the first days by a steady but slightly accentuated delivery, in which all the syllables are pronounced without precipitation, and, above all, without jerking.

During this last week, Chervin counsels his pupils to imitate persons who speak well; whose delivery, without being of pedantic slowness, is calm and deliberate; in whose voice the inflections are natural and varied; whose sentences, well modelled, both as to breathing and meaning, are easy to understand and pleasant to hear.

But at the expiration of the three weeks it must not be supposed that the pupil is entirely cured; he is like a convalescent, who has still need of care and precautions in order to achieve a complete restoration. Special instructions must be given to him, whereby he may be able to continue the application of the method, and thus indelibly fix the habit of speaking properly.—*New Orleans Medical and Surgical Journal*, July, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 24, 1886.

THE TREATMENT OF DIVIDED TENDONS.

FOR the treatment of tendons ruptured subcutaneously, the majority of the text-books on surgery recommend simple attempts at approximation of the separated ends by position, and, in the case of an open wound, suturing the separated ends. The former method has been very often adopted, with moderate success, and the latter has been used often enough, and successfully enough, to make it a well-established plan of procedure. In 1882, however, HEUCK reported, in the *Centralblatt für Chirurgie*, a plan adopted with success by Czerny, which may be regarded as an improvement upon the methods just mentioned. In this case, Czerny, finding it impossible to bring together the ends of a subcutaneously ruptured extensor of the thumb, two weeks after the accident, did a sort of flap operation, which resulted in restoration of the power of extension of the thumb. Whether this was effected by direct union of the divided ends of the tendon, or by means of their union to the cicatrix in the skin, it is not easy to say.

Still another method of overcoming the difficulty presented by wide separation of the ends of a divided or ruptured tendon is what the French have called "union by anastomosis." This consists in grafting the peripheral end of the injured tendon to the continuity of a neighboring sound tendon. The operation has been done only a few times; but it has proved so successful as to merit attention. The first account of its performance is somewhat apocryphal. Velpeau is said by Tillaux to have mentioned two such operations done by Missa and Champion. The earliest authentic case is said by Denonvilliers, in the *Bull. et Mém. de l'Acad. de Chirurgie*, for 1875, to have been done in 1873, by Polaillon, who sutured the peripheral ends of the divided extensor tendons of the three middle fingers to the corresponding tendons of the thumb and little finger. In 1875, Tillaux reported to the Academie de Chirurgie a successful operation, done in 1874, in which, two months after the division by laceration of the extensor tendons of the little and ring fingers, he cut down upon them and sutured their peripheral ends to the extensor tendon of the middle finger. In 1876, Duplay reported to the same society a case in which he had successfully united the subcutaneously ruptured tendon of the long extensor of the thumb to the tendon of the extensor carpi radialis longior, by inserting the peripheral end of the former into a buttonhole made in the latter, and fixing it there with a single wire suture. At the same time, Tillaux reported that he had just done an exactly similar operation.

The most recent writer on this subject is HAGER, who, in the *Berliner klin. Wochenschrift*, for May 31, 1886, describes an operation for the relief of what he calls, after Volkmann, a spontaneous rupture of the tendon of the long extensor of the thumb. The operation was done in 1885, and consisted in cutting down upon the tendon seventeen days after the rupture occurred, and attempting to find the divided ends. Failing to discover the upper end, because of its retraction, he cut the lower end off obliquely, and sutured it with catgut to the tendon of the extensor indicis, after having opened the sheath of the latter and freshened a suitable surface by scraping off the epithelium. Under antiseptic treatment the wound healed by first intention, and in two months the power of extending the thumb was almost restored, while in six months the movements of the hand were nearly normal, the thumb moving freely even when the fingers were flexed into the palm so as to make a fist.

This admirable result confirms the previous experiences which we have mentioned, and encourages the hope that in this method we have a means of repairing an otherwise hopeless injury.

THE USE OF THE STOMACH PUMP IN INTESTINAL OBSTRUCTION.

A RECENT paper by CAHN, in the *Berliner klinische Wochenschrift*, for May 31, 1886, gives an interesting account of a case in which a large sarcoma of the retroperitoneal glands produced symptoms which might easily have been judged to be those of cancerous stricture of the pylorus. In fact, the diagnosis of carcinoma was made, but the position of the tumor was believed to be below the pyloric orifice and beyond the opening of the common bile-duct into the duodenum. The correctness of this opinion as to its location was demonstrated at the autopsy,

and it is of peculiar interest to note the fact upon which the opinion was based during life, viz., that when the stomach was washed out by means of the tube, large quantities of bile were evacuated, either pure, after the contents of the stomach were removed, or mixed with intestinal contents.

Leichtenstern has called attention to the significance of the persistent admixture of bile with the vomited material in cases of suspected stenosis of the pyloric orifice, but in the case reported by Cahn there was no bilious vomiting, it was only after the stomach had been cleared of its contents by the tube that bile was able to enter it at all, and then it was removed by the tube. Cahn explains the absence of bile in the stomach before the use of the tube by the fact that the presence of undigested material in the stomach acts as an irritant and causes unremitting vermicular movements, with more or less tonic contraction of the circular fibres at the pyloric extremity, and that washing out the stomach reduces the intragastric pressure, and removes the cause of the spasm which prevented the passage of bile or other contents of the duodenum into the stomach. Cahn's observations suggested to him that washing out the stomach may prove useful not only in locating the seat of an obstruction in the digestive tract, but also in furnishing relief for some of the distress to which such an obstruction may give.

A practical application of these principles was observed by Kussmaul in a case of intestinal obstruction treated by washing out the stomach. This operation relieved the patient of large quantities of fecal matter which had found their way into the stomach, and this relief seems to have led to some change in the state of excitation of the muscular coat of the bowel, so that enemata, which had been unsuccessfully used before, now brought away masses of feces, and the patient recovered. In this case, it is proper to remark, the symptoms reported indicate that the condition was probably due to enteritis and not to intussusception.

Cahn also records two cases, occurring in the practice of Lücke, in which the symptoms of ileus followed the operation of gastroenterostomy, and were relieved by washing out the stomach; and he points out the advantage of this simple means of overcoming a dangerous complication of this operation.

The opinions of Cahn, as to the service which washing out the stomach may render, are deserving of careful consideration and their application to practice may develop important results in regard to the diagnosis and treatment of obstructions in the digestive tract.

AORTIC ANEURISM TREATED BY WIRE AND GALVANISM.

In The Medical News for December 12, 1885, and March 27, 1886, we made some remarks upon the treatment of aneurisms of the aorta by the introduction of filiform materials. We cited a case operated upon by Loreta, in 1884, which must be considered as a success so far as the consolidation and diminution of the tumor are concerned, and another treated by Cayley, Hulke, and Gould, in 1885, in which the result was at least temporarily successful. And now Barwell reports in the *Lancet* for June 5, 1886, a case of aneurism of the arch of the aorta involving its lower aspect, in which he ingeniously combined the introduction of filiform material and the application of galvanism. He introduced, through an ivory stylet, ten feet of the finest steel wire, which had previously been coiled on a wooden cylinder half an inch in diameter. The end of the wire was connected with the positive pole of a battery. The negative pole was applied to the upper dorsal region of the patient, with a piece of amadou about a foot square, thoroughly saturated with hot water, between the electrode and the skin. By means of a galvanometer the strength of the current was measured, and found to be not more than four milliampères. This was then brought up to nine or ten milliampères, and passed continuously through the circuit for an hour and ten minutes. At the end of twelve hours the pulsation in the tumor seemed to be more distant, and the tumor much harder. Signs of bronchial obstruction, which had been very distressing before, were lessened. On the fourth day after the operation a new tumor was found on the other side of the sternum, and four days later the patient died from rupture of the second sac, two and a half pounds of blood being found in the right pleural cavity at the autopsy. The main aneurismal sac contained large wide coils of wire, each of which was surrounded by a "pretty thick" coat of firm, colorless fibrin, strongly adherent to it, and wherever the metal was in contact with, or within a moderate distance of the wall, the wire was bound to the sac.

In studying this case we must admire the ingenuity of the operator, and share his opinion that there appears to be a decided theoretical advantage in attempting to cure aneurism by combining the coagulating power of electricity with that of foreign substances introduced into the blood current. We think, however, that the appearances we have cited, as found in the sac of the aneurism at the autopsy, do not indicate that the use of galvanism in conjunction with the introduction of fine wire is, in any sense, to be preferred to the use of filiform material alone, although the experiment is deserving of further trial. We would, however, suggest that the quantity of wire introduced into the aneurismal sac in this case was too small. Mr. Hulke introduced forty feet of wire in his case, and Mr. Gould afterward introduced nearly thirty-five feet of wire in the same case.

EXERCISE AND OVER-EXERCISE.

In the river at New London, lately, occurred a series of boat races between representatives of four universities. The sympathetic and more or less excited audience saw numerous perspiring youths tugging manfully at the oar, and heard loud college cheers echoed along either shore, and those of its members who were not too old or too *blasé* felt something of the enthusiasm which urged on the long, narrow "shells" toward the finish. Men who had once held an oar, renewed, for a moment, in that struggle, similar contests of bygone days, when they had helped to pull their "'varsity" to the fore. But who, of all the spectators, old or young, appreciated what this contest meant to the participants? The on-looker perceived the heat of a day in June. He beheld a pleasant river, whose green banks were dotted with varying bits and splashes of color. He saw a wild, rushing "burst of speed," and heard ringing cheers growing louder as the boats flashed up to the goal. To each member of the crews, however, those few moments of that summer afternoon were the climax of months of hard, steady work. Their training for that race meant long weeks of self-control, and it meant steady, systematic, mechanical exertion continued day after day; yet all this time their college duties must not be neglected. Then comes the race! "How easily they row! It does not seem like work," one hears from a looker-on. But they *are* working. Each man in the boats has forgotten, for the time, that he is an anatomical collection. He has forgotten that within him is a heart and lungs. He thinks not of the proper balance between cell degeneration and cell growth. He has become a human will, which is to prove itself a hard taskmaster over its servant members.

Woe to any one of them if his strength be not sufficient. What if the heart, first hypertrophied and then strained, by hard exercise, is just on the border of dilatation? The brave will drives on in spite of the pumping, spasmodic, irregularly bounding organ, until the finish line be passed and the man, perhaps, falls unconscious over the handle of the oar which he has so bravely grasped. Will Da Costa's "irritable heart" account for his symptoms of the following month, or are they the beginnings of more serious trouble? There is the same forgetfulness of self in all athletic contests, a firm demand for more power than the body can supply. Hence it becomes extremely important to select only picked men, to watch daily the effects of judicious training upon them, to drop out every case in which signs of weakness are indicated, and, at last, to find the few "elect" who can bear the burden and heat of the day.

Are college crews or other contestants thus selected? In a few instances there are judicious and competent men in charge of their physical training. In many cases this is left to a professional oarsman or general athlete, assisted by a committee of the college students or of the club. They pick out the most "likely" men available. Occasionally these are examined as to chest condition—more frequently they are not. Even when examined, there is seldom any careful inspection of the effects which daily exercise is producing upon these candidates for athletic honors. It is by such oversight that the men slip into crews who "pull their hearts out in the race," and who break down, even years afterward, from any light exertion.

Athletic contests are to be encouraged. They cultivate all the manly qualities, and tend to produce a sound mind as well as a sound body. To attain this worthy result, however, there is need for intelligent medical direction, and without this there is every probability that they may prove most baneful both in their immediate and remote consequences.

REVIEWS.

The Surgical Diseases of Children. By Edmund Owen, M.B., F.R.C.S., Surgeon to the Hospital for Sick Children, Great Ormond Street, London. 12mo. pp. 585, with 4 chromo-lithographic plates and 85 engravings. Philadelphia: Lea Brothers & Co., 1886.

This is an admirable treatise, well suited to form one in a series of handy manuals for ready reference. The arrangement is all that can be desired, and the wide field of children's diseases ordinarily regarded as coming within the province of the surgeon is gone over with more or less thoroughness. Necessarily some subjects are treated with brevity, but others are gone into with considerable fulness. Nor has the work been hastily prepared, for almost every page bears testimony to careful research, and the compilation of recently proposed plans of treatment is full. There are many points upon which we might dwell in detail, but we will confine ourselves to mentioning the subject of hip-joint disease, which is treated at considerable length in a separate chapter. Mr. Owen holds that, while the majority of cases have an origin in early injury, many cases occur in which no such cause can be made out. The method of making a diagnosis is detailed with care, and we are pleased to observe, both in this connection and elsewhere, the stress Mr. Owen lays upon gentleness as an aid to arriving at a correct and accurate conclusion in the diseases of children. Not that gentleness should ever be neglected in any case, but Mr. Owen points out that their susceptibility and timidity make it especially important in children. The extreme importance of rest in the treatment of these cases, especially in the early stage, is dwelt upon, and the value of extension by a weight is recognized, but Mr. Owen is an enthusiastic advocate of Thomas's splint, properly appreciating the value of the fresh air which its application will enable the patient to get. Nor would we say anything against that splint or the similar one devised by Dr. Agnew, but we have never yet seen the apparatus which will secure as perfect quietude, while the patient

is going about, as can be obtained in bed. We have not found it necessary to keep up perfect extension of the joint by compelling the patient to be perfectly still, as Mr. Owen suggests, but obtain very satisfactory results when the child is allowed to sit up partially and amuse himself with toys and books on a bed-table. When cases are seen early and thus treated, we have seen no occasion to resort to any other means of treatment. Of course, tonics and fresh air, obtained by moving the bed out-of-doors in suitable weather, are invaluable adjuvants. Mr. Owen has incorporated in his book sections on embryology bearing upon the various topics in hand. The illustrations, if not very fine, make the author's meaning quite clear, and we have no hesitation in commending the volume as valuable and trustworthy, containing, as it does, a vast amount of information in very small compass.

SOCIETY PROCEEDINGS.

CHICAGO GYNECOLOGICAL SOCIETY.

Stated Meeting, May 28, 1886.

THE PRESIDENT, DANIEL T. NELSON, M.D., IN THE CHAIR.

ABDOMINAL SECTION FOR PELVIC ABSCESS.

The Secretary read the following letter:

7, THE CRESCENT, BIRMINGHAM,
April 14, 1886.

If not too late, I should like to take part in the discussion which was entered into at the Gynecological Society of your city upon abdominal section for pelvic abscess. My remarks, of course, are discursive and not very conclusive, because they are based upon only a very few points to which I want to draw attention.

The first is this: I object to the use of words ending in *otomy*, to mean various operations all of which are practically identical in character but different in detail and not one of which can have any exclusive or absolute identification by any particular name. Thus Professor Christian Fenger, in the discussion, objects to the use of the word laparotomy, and he introduces another which is perfectly new to me and I hope it will never be used again: it is *oncotomy*. Dr. Fenger objects to laparotomy in a sense where I certainly have no objections, and his very objections only show how utterly absurd all these words are. There really ought not to be any such word as laparotomy in existence, because the signification of its derivatives in the use of the people who spoke the language is such that it could not by any human ingenuity be applied to any modern surgical proceeding. Now the words "abdominal section" are sufficiently English to be understood by everybody, and they are sufficiently distinctive to enable us to understand at once that when they are used the peritoneum is opened. I therefore wish, through your powerful society, to protest against the use of all these stupid words of Greek formation. I wish also to protest against the absurd distinctions drawn by Sänger, which are quoted by Dr. Fenger on the subject of pelvic abscess.

He distinguishes six kinds of salpingitis:

1. *Septic*, the existence of which I entirely dispute as a specific ailment.

2. *Tuberculous*, which again I deny, except that it has an existence as the third and contracting stage of pyosalpinx.

3. *Syphilitic*, not one particle of evidence of this have I ever seen.

4. *Actinomycotic*, which is an equally ridiculous subdivision, based on mere theory, not on fact.

5. *Gonorrhœal*, to which the great bulk of the cases belong.

6. *A mixed form.* Instead of this sixth, or mixed form, I would say that there are a great many cases to which we cannot attribute any actual origin, a number of cases occurring in virgins where the existence of gonorrhœa would be an impossibility, and where there was no puerperal mischief.

Dr. Fenger's paper has always seemed to me to be an illustration of the German savant evolving the descriptions of the camel out of his own consciousness. My descriptions, on the other hand, are taken from some hundreds of cases upon which I have performed operations and the history of which I know as completely as it is possible to obtain information.

In Dr. Reeves Jackson's paper there are two points to which I want specially to draw attention, and they are not of much importance because they are chiefly questions personal to myself.

The first is a passage in which it is said "Lawson Tait, of Birmingham, and Martin, of Berlin, were the first who attempted to prevent the terrible contingencies of pelvic inflammations by attacking the disease at its original seat; Lawson Tait removed the suppurating uterine appendages, Martin operated for suppurating periuterine hæmatocele. Tait operated for suppurating hæmatoma of the right Fallopian tube in 1878, and he removed both tubes for pyosalpinx, and an ovary for abscess in 1885. In 1885 Martin performed laparotomy in three cases of intraperitoneal hæmatoma, namely, retrouterine hæmatocele." Now accuracy of date in a matter of this kind is rather important for one's own personal reputation, and Professor Reeves Jackson has underestimated my claim for priority by at least seven years. The first operation which I performed for suppuration of the uterine appendages was done on the 11th of February, 1872, and there will be found in the last edition of my book on *Diseases of the Ovaries*, twenty-two cases which I had performed up to the middle of August, 1882, without a death. Since then I have operated upon hundreds. The first case of suppurating hæmatocele which I operated upon is published in detail in the same book; it was in February, 1879, and since then I have operated upon thirty-two cases without a death, and all have been completely cured. It will thus be seen that in none of these matters have the German surgeons approached English surgery as rivals in priority. They have been mere followers in every particular, and I regret to say their following has been practised without that recognition to which our priority gives us every just claim.

The second point is that in which I find Professor Byford speaking in terms of my own work which no words of mine can sufficiently recognize or express my appreciation of, and here certainly his words of caution are worthy of a little note. What I fear—in fact, what I already feel—is that the remarkable success which I have had, and of which Professor Byford speaks in such

strong terms, is really leading astray those whose opportunities have not been as my own, into the belief that the work is easy, simple, easily acquired, and free from risk. It is not so, and unless those who practise it choose to follow me in the rigid precautions and immense care which I give, not only to the mere performance of the operation, but to the surroundings of my patients and to every detail in connection with them, they will not obtain, they must not expect, the success which I have had. I have said that I fear—in fact, I already feel—that this success of mine is leading people astray, and I want to urge in the name of humanity, as well for the sake of the art we practise, that there should be less of the indiscriminate rushing into this kind of work which has been already deplored on both sides of the Atlantic. I am, etc.,

Lawson Tait.

Dr. Christian Fenger said that the letter of Mr. Lawson Tait relates in a number of points to his paper on "Laparotomy for Periuterine Abscess" as well as to some remarks which he made before the Society in a previous discussion. (See The Medical News for March 27, 1886.) He, therefore, begged the Fellows of the Society to bear with him while he took up a little of their time in answering Mr. Tait's letter. When discussing Professor A. Reeves Jackson's paper, he objected to calling the operation in question a laparotomy. According to the Professor's description of the case, he had opened an abscess which was adherent to the anterior abdominal wall. He had consequently simply performed an oncotomy, an operation which, notwithstanding the division of the abdominal wall, does not differ materially from opening a deep-seated abscess in any other region of the body, as *e. g.* in an extremity. Whether opening the abdominal or peritoneal cavity be termed laparotomy or abdominal section or *Bauch-Schnitt*, is, of course, a matter of indifference, provided only that the meaning of the word be agreed upon. There is but one way of getting at the signification of a medical term, and that is by learning in what sense the term is employed in the medical literature of the different nations.

He must again maintain that laparotomy is not merely section of the abdominal parietes, but that the word implies the opening of the general peritoneal cavity with a view to perform some operation within that cavity. (See Linhardt's *Operationslehre*, Wien, 1862, p. 705; and Eulenburg, *Realencyclopædie*, Bd. ii. S. 37.) French authors occasionally use the word gastrotomy instead of laparotomy. Recently the operation has been called peritonotomy, which, on account of its correctness, should perhaps be preferred to the other terms.

It is of importance to distinguish between a laparotomy and the evacuation of a limited abscess by simply incising the abdominal wall. The two operations differ widely as to their consequent dangers. Where the general peritoneal cavity is opened, a well-known series of precautionary measures is required before and during the operation, in order to protect the patient from general septic peritonitis. Where an incision through the abdominal parietes leads directly into a limited abscess cavity, the precautionary measures essential to laparotomy may be dispensed with; the general peritoneal cavity is not opened, and there is no fear of general peritonitis. In the latter operation the peritoneum is not seen or not noticed, the incision wound is left open, and the limited cavity washed out and drained. In every country, medical authors hold these two operations apart. Opening a perityphlitic abscess, an adherent hepatic abscess or a parametritic abscess above Poupart's ligament is never spoken of as a laparotomy. Whenever we hear or read of a man having performed a series of laparotomies, we naturally suppose that he is experienced in performing intraperitoneal operations. Now, many a surgeon has opened a large number of intra-abdominal abscesses, and has never seen the peritoneal cavity. It is evidently important properly to limit the meaning of the term laparotomy; else we may misunderstand the description of a given case, and the statistics of laparotomies will necessarily be rendered valueless.

The next point Mr. Lawson Tait remarks upon is the question of priority of operating for pelvic hæmatocele.

By the mistake of Mr. Tait, part of what he said in the discussion of Professor Jackson's paper is ascribed to the paper itself. He was thus quoted in Mr. Tait's letter:

"Lawson Tait, of Birmingham, and Martin, of Berlin, were the first who attempted to prevent the terrible consequences of pelvic inflammations by attacking the disease at its original seat. Lawson Tait removed the suppurating uterine appendices; Martin operated for suppurating periuterine hæmatocele."

In the discussion he stated the dates at which Tait and Martin performed their respective operations. By a typographical error the dates appeared wrong in some of the copies of the transactions of the Society. 1885, instead of 1872, was given as the date of Tait's first laparotomy for abscess of the ovary; and 1885, instead of 1876, as that of Martin's first laparotomy for extraperitoneal hæmatocele. Considering his remarks as a whole, and examining his references to the literature on the subject, a careful reader would not have failed to recognize in the wrongly printed dates a typographical error.

Lawson Tait performed his first laparotomy for extraperitoneal hæmatocele in February, 1879. (See *Diseases of the Ovaries*, 4th edition. London, 1883, p. 346, and Tait's letter.) Martin performed the same operation for the first time in 1877, and a second time on the 31st of January, 1879. (See *Das Extraperitoneale Periuterine Hæmatom. Zeitschrift für Geburtshülfe und Gynäcologie*, 1882, VIII. Bd., Heft ii., S. 476.)

It will thus be seen that his statements concerning priority were correct. In the discussion of Professor Jackson's paper, he quoted Sänger's classification of pelvic inflammations. In criticising it, Mr. Lawson Tait speaks of "absurd distinctions." He wished to repeat that he regards Sänger's classification as complete and correct, and in accordance with the laws governing inflammatory processes in all organs of the body.

Dr. Charles T. Parkes then read a paper on

Uterine Fibroids Treated by the Fluid Extract of Ergot.

He related the history of four cases of uterine tumor, treated by the internal administration of Squibb's fluid extract of ergot. They all resulted in recovery by expulsion of the growth.

He found no insurmountable difficulty in giving the medicine, although when given for a prolonged period it creates nausea and disgust in some. This was counteracted, and the pain following its use controlled by combining it with morphine. It seemed to him preferable to the hypodermatic use, the latter being locally painful and often producing abscess; besides, it is not followed by any better result. In two of the cases treated by ergot, the tumor, when thrown off, proved to be true uterine fibroma — dense and hard, white and glistening when cut open, consisting of simple fibrous tissue. The other two following the action of ergot were soft myomata — pultaceous and semi-elastic—consisting mostly of connective tissue, confirming the diagnosis made. All four of these were evidently submucous tumors, or so slightly interstitial as to be practically covered only by mucous membrane.

Case I.—Mrs. S., American, forty-three years old, widow, three children, no miscarriages, menstruated first when sixteen years old. Never had any noticeable trouble with menstruation until three years previous to first examination; during these years she had suffered with irregular profuse hemorrhages which were now continuous, accompanied with exacerbations on the slightest exertion. His first examination was made February 20, 1876, at which time she presented the most perfect example of transparent flesh that he had ever seen. A large, finely formed woman, her flesh looked like alabaster, apparently destitute of blood. The legs were œdematous, the heart beat feeble and rapid, and the slightest exertion was followed by extreme palpitation and the most fearful feelings of suffocation. Her answer as to what she had done for her trouble was that she had taken "quarts of medicine." Vaginal examination revealed an enlarged uterus and patulus os, from which blood was rather freely oozing. The sound entered the uterus about five inches, the handle being deviated forward and to the left side. A diagnosis of submucous uterine fibroid was made.

The treatment adopted was the administration of strychnia and iron, together with wine and good diet for the general condition, and one-half drachm doses of Squibb's fluid extract of ergot every six hours, either to expel or kill the growth. Locally, to stay the hemorrhage, a small tampon of pulverized alum was applied to the *os uteri* and held in position by ordinary cotton tampons.

The first forty-eight hours' use of the ergot produced quite severe uterine pains, so acute that the patient, in her weakened condition, said they were unbearable. At this visit Professor T. D. Fitch saw her in consultation. The tampon of alum was removed, and Dr. Fitch's examination confirmed the diagnosis made, and advised the continuation of the treatment. As the bleeding had been entirely controlled by the tamponade, it was left out. The ergot was continued as before, and a sufficient dosage of morphine ordered, to make the pains bearable if they persisted. No further use of the tampon was required, the uterine contractions never ceased while the ergot was administered. On the sixth day of its use a foul-smelling serous discharge came on *per vaginam*, accompanied with slight general chilliness and a temperature of 102° F. The patient was assured that the tumor was surely coming away, and encouraged to bear "yet awhile" with her great suffering. On the eighth day the tumor was found in the vagina and removed. It was about the size of a duck's egg and very hard to the touch. After a short period of mild septic trouble the patient passed through a quick convalescence and rapidly recovered. Seen a few months ago, she says she has never had any illness since getting rid of this growth, and certainly looks well.

Case II.—Mrs. P., German, married, five children, no miscarriages, menstruation began at fourteen, now thirty-seven years old. Seen first in March, 1881. The patient is a robust, hearty woman. Never had any trouble until six months after the birth of last child, about one year ago, when she began to flow too freely and too often—as often as every week or occasionally twice a week. The blood was in large quantity and bright red in color.

The examination revealed an enlarged uterus—it could be felt above the pubis during bimanual examination. The sound entered easily for five inches, the handle deviating forward and to the left. Its use was accompanied and followed by very free bleeding.

Diagnosis: Submucous uterine fibroid on anterior wall. Treatment: locally the alum tampon was used as in the previous case. Squibb's fluid extract of ergot in half drachm doses every six hours. The patient was ordered to remain in bed. On the succeeding day all the tampon, except the alum, was removed. No hemorrhage; slight pains complained of. On the second day the pains were very severe and morphine was given to control them. The alum tampon was removed and a carbolized hot water injection ordered three times a day. On the third day pains still severe and a foul-smelling vaginal discharge commencing.

This condition persisted until during the night of the eighth day, when he was summoned to the patient on account of the unusual severity of her sufferings, the messenger, her husband, saying it was just as if she were in labor. On his arrival the pains had quite ceased. Examination showed the loss of considerable blood, and the vagina was found filled with a large fleshy mass, horribly offensive. The finger could be passed beyond it, and the largely opened cervix recognized. It was seized with a vulsellum forceps, twisted a few times upon itself, and then delivered. The mass was as large as a closed fist, dark colored, ragged all over its surface, and very foul smelling. The patient rapidly regained her usual health, and is well to-day.

Case III.—Mrs. E., thirty-three years old married, three children living, one miscarriage; menstruation commenced when fourteen years of age. Was first called to visit her January 2, 1885, for severe uterine hemorrhage. She never had any trouble with menstruation until about two years previous. Shortly thereafter she was operated upon for laceration of the cervix, without much relief to her trouble; since, she had gradually grown worse, so that she was not free from bleeding ten days in the month. One year previous to seeing her, the uterus was freely curetted and fuming nitric acid applied to the cavity to relieve the bleeding. This procedure failed in any good result.

At this visit the bleeding was extreme in degree. Examination revealed the pelvis largely filled with a smooth, doughy mass. After considerable searching the *os uteri* was found high up above and close to the pubis. It could only be found by crowding the finger

between the bone and the growth. The growth was exquisitely tender to the touch or any manipulation. Bimanual palpation discovered an uncertain mass above the pubis. The vagina was tamponed temporarily, and morphine administered hypodermatically. The diagnosis was reserved. It rested between hæmatocele and soft myoma. The tumor was compressible, at least its elements seemed to give way to the pressure of the finger; it was semi-elastic and painful under manipulation, filled the entire posterior half of the pelvis, and the os was carried well upward forward. It might be, and probably was, a myoma of the posterior uterine wall retroverted.

A few weeks ago he had the satisfaction of seeing the *fac simile* of this case, so far as the character of displacement and the position of the tumor was concerned in a patient under the care of Dr. Merriman, although the tumor in Dr. Merriman's case was much harder and more resistant. Dr. Merriman, with skill and apparently with ease, lifted the tumor out of the pelvis into the general abdominal cavity, after placing the woman in the knee-elbow position—a change bringing much comfort to the patient. Under the use of ergot the growth is diminishing in size.

The patient was put upon fluid extract of ergot in half drachm doses three times a day. The next menstrual period showed no change other than a diminished loss of blood. In June the flooding was quite free and accompanied with considerable pain. In July everything was as bad as possible, with so much pain that the ergot was discontinued. Repeated examination now narrowed the diagnosis down to soft myoma. The removal of the uterine appendages was suggested, in the hope that this procedure would anticipate the menopause, stop the bleeding, and lead to the gradual atrophy of the growth. In September consultation was solicited with Prof. W. H. Byford, when the patient was etherized and carefully examined. The sound, introduced with great difficulty, owing to the displaced position of the os, passed in over five inches, positively demonstrating the nature of the growth, its consistency showing it to be the soft variety of myoma. As the patient could not be said to be in danger of her life, the operation was refused by her friends, although the sufferer was willing enough to have it done.

The previous treatment was endorsed by Prof. Byford, and its continuance advised. The fluid extract of ergot was resumed and rendered bearable by morphine. The October illness was accompanied by slight hemorrhage, but excessive pain. These uterine contractions continued after the menstruation ceased, until, during the last week of October, they became labor-like in character. Examination now revealed that the uterus had righted itself, the os was becoming patulous and its edges thinned out; through its opening the projecting tumor could be felt. On the second day of November pieces of the broken-down mass, horribly offensive, could be seized with the forceps, pulled out of the uterus, and cut away.

Chilly sensations began to be felt by the patient, sweating came on, temperature ran up to 101° F., and a mild septicæmia was established. During the following week the pains never ceased. Quinia was administered freely. The vagina and uterus were irrigated with hot carbolized injections, and portions of the mass removed as fast as they could be reached; at the end of a week the last remnant was gotten away. The patient was very much reduced physically, but rapidly convalesced, and is now perfectly well, with her menstruation normally reëstablished. Fully a quart of soft pultaceous pieces of the growth was removed.

Case IV.—Mrs. L., German, thirty-four years old, one child, was seen first November, 1885. She had been suffering with increased menstrual flow for a year. She came to me to be treated for an external, painful, labial swelling. It proved to be a vulvo-vaginal abscess. It was opened freely, and gave no further trouble. A uterine tumor was noticed and examined. It was found to be of considerable size,—could be detected above the pubis. She was put upon one-half drachm doses of fluid extract of ergot every six hours. This she continued for six months steadily, with varying conditions of pain and hemorrhage, until, in April, 1886, the hemorrhage ceased, pain became very severe, and a shreddy, foul-smelling discharge manifested itself. She was removed to the St. Joseph's Hospital, and after ten days of antiseptic washings and removal of masses of broken-down tissue, the mass was entirely extruded. This patient had also quite a severe septicæmia, but finally recovered, and is now well.

Aside from crucial demonstration, it seems reasonable to assert that these four cases were cured by means of the remedy used, and by that alone. It is well known that most authorities state that no positive reliance can be placed on the use of ergot. His experience surely, as here illustrated, and confirmed by other cases seen, leads him to think that this adverse judgment must be qualified, especially in the treatment of the submucous bleeding fibroids of the uterus. If the growths be partially interstitial, the less the thickness of uterine tissue between them and the mucous covering, the more certain will the remedy be curative. Of course, it will be impossible to demonstrate the exact amount of uterine wall which forced contractions will destroy; hence a trial is desirable in all cases not purely subperitoneal and pedunculated. Still he is quite convinced that the severity of the hemorrhage gives one a good reason to speak *positively* of the results to be accomplished by its use. He has not deemed it necessary to look up the history of the first use of this remedy for stimulating uterine contractions. It is sufficient for him to say that his confidence in the remedy and persistence in its use, even when failure of good results seemed certain, has followed directly as the result of the teachings and experience of Prof. Wm. H. Byford, who has never lost an opportunity to urge upon the profession his belief in the specific action of the remedy, and its absolute certainty of cure in many cases. He is quite sure that Prof. Byford deserves the credit of being the first to make use of ergot with the idea of destroying the vitality of the growth, and, in addition, causing its expulsion from the uterus.

The third case shows plainly how absolutely unnecessary any operation would have been. The removal of the appendages might have stopped the hemorrhage, but such a perfect cure as now exists could never have followed operation, to say nothing of the harm done by unsexing the woman; still, no case could present better reasons for such a procedure, none in which it would have been more justifiable from the indications present.

To him it brings the lesson to make oöphorectomy the *dernier ressort* in all cases, certainly to give the remedy used at least a six months' trial without result before operation be sanctioned.

The difficulties attending the differentiation between a sac of fluid and the soft myomata was well illustrated by this case. The sensation communicated to the touch was scarcely distinguishable from fluctuation. It was only after repeated examinations under ether, and the use of the sound, that the diagnosis was satisfactorily settled.

The fourth case for a time seemed one in which the treatment would come to nothing. Every one became discouraged. The suffering was increased, and no advance was made, apparently. By persistence the cure was accomplished. In this case operative interference was solicited by the patient, and would have been most readily submitted to, without any urging. He read aright the indications which authorities give, to justify the resort to removal of the uterine appendages; they were all present in this case, and more too if needed. Certainly the final result has proven that such interference would have been uncalled for and lamentable.

He was quite well aware that four cases cannot be considered absolutely demonstrative of any rule, still these four increase the number already published in proof of the curative action of ergot, administered thoroughly, for submucous uterine growths. It is impossible for him to understand how some good authorities can still assert their disbelief in ergot; in fact, calling it the most inert and disappointing of all drugs. No law has as yet been evolved fixing even by approximation the period of time required for the effects of the medicine to show themselves. The idiosyncrasies of the patient, the thickness of the uterine envelope, the distance from the mucous membrane, the purity of the drug, and many other conditions, render it scarcely possible that any such law can ever be laid down. The trial should be made patiently aud persistently, just so long as the patient's condition will warrant its continuance, and a complete expulsion of the growth, followed by rapid recovery, will be the reward.

Dr. F. E. Waxham read a paper on

OCCLUSION OF THE OS UTERI AS AN IMPEDIMENT TO LABOR, WITH A REPORT OF TWO CASES.

Having met with occlusion of the os but once in several hundred cases of labor, and knowing of a number of physicians in extensive practice who have never seen this condition present at the time of confinement, he is convinced that it must be of rare occurrence, and the history of two cases may not be uninteresting.

Mrs. S., German, primipara, twenty-nine years old, fell in labor about 9 P. M., February 21, 1885. The membranes ruptured soon after the commencement of labor and the amniotic fluid gradually drained away.

The patient was seen between 3 and 4 A. M., at which time the pains had become very severe and frequent. Upon examination the head was found low down in the inferior strait, almost presenting at the vulva, and covered apparently by a thin membrane through which the advancing head threatened to burst with every pain. Upon the most careful digital examination, no os could be discovered nor the slightest indication of one. Professor Nelson was summoned and promptly responded. His more experienced finger detected a very slight dimple in the centre of the presenting tissues. By keeping the finger upon this slightly thickened tissue, he discovered that it became very much thinner with every pain, while as the pain subsided the tissue assumed a very slightly umbilicated appearance. By firm and continued pressure upon this suspicious spot an opening was at length effected and the os gradually dilated. As the labor proceeded slowly, and fearing the result to the child of so long a delay of the head in the pelvis, and the os being fully dilated, the forceps were applied. The child was delivered without injury to the mother, but it was asphyxiated and required considerable effort in resuscitation. Professor Nelson stated that this was the second case that had come under his observation, and kindly gave him the history of the following one. He was called to attend a lady in her first confinement, a Swede, twenty-three years old, and married about one year. Making a hasty examination, he found a well-formed cervix but did not detect the os. On returning a few hours later, the head had descended to the inferior strait and was indeed presenting at the vulva and covered by the cervix, which had become so thin as to resemble the membranes. The membranes had already ruptured and the amniotic fluid had gradually escaped. There was no appearance whatever of the os. It could not be detected by the finger, and the head seemed about to burst through the uterine tissue. The patient was placed before a window, the labia separated and careful search made for the os. Only after a prolonged examination was it found. It was patulous only to the extent of admitting the very finest surgeon's probe. After this had been introduced and worked about, a second probe was passed, and by separating them the os was gradually and sufficiently dilated to allow the finger to enter. The os was then rapidly dilated and labor progressed normally.

Dr. Waxham finds the literature on this subject quite meagre, many writers on obstetrics omitting the subject entirely, while others refer to it very briefly.

All authorities agree that the occlusion of the os is the result of inflammatory change occurring subsequent to impregnation. It is a noteworthy fact that in both these cases the membranes ruptured and the amniotic fluid escaped in the very early stages of labor, showing that the membranes were adherent to the uterine tissue about the internal os. As the internal os dilated, rupture of the adhesions and of the membranes necessarily followed.

ELECTION OF HONORARY FELLOWS.

Mr. Lawson Tait, of Birmingham, and Professor T. Gaillard Thomas, of New York, were elected Honorary Fellows of the Society.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, May 24, 1886.

The President, James T. Whittaker, M.D., in the Chair.

(Continued from page 81.)

Dr. James G. Hyndman, in introducing the subject of

THE CHEMISTRY OF ECHINOCOCCUS,

said that numerous investigations have been made of the wall of the echinococcus cyst as well as of the con-

tents. While a knowledge of the nature of the wall will probably never be of any considerable clinical value, it should nevertheless be referred to in the discussion. It is described as being sometimes delicate and of a dull white color, at others very substantial and translucent; of about the consistence of coagulated albumen and divided into distinct lamellæ. It consists, according to Heller, of a substance resembling chitin, but whether actually chitin or not has not been positively determined. Its insolubility in caustic alkalies and dilute acids has led to its classification among those substances of chitinous composition. Chitin is a colorless, amorphous body which is insoluble in water, alcohol, ether, acetic acid, dilute mineral acids, and in solutions of the caustic alkalies. Its composition is believed to be $C_{15}H_{26}N_2O_{10}$. The researches of Hoppe-Seyler and Baumann have shown that, when heated with acids, chitin combines with the element of water and splits up into a nitrogenous body, glycosamine and acetic acid.

Investigators have rendered our knowledge of the chemical constitution of the echinococcus cyst contents far more accurate than that of the cell-walls. A summary of the chemical examinations made by a number of competent observers gives the fluid the following characters: It is colorless, contains from 1.5 to 2 per cent. of solids, and has a specific gravity varying from 1.007 to 1.015. It contains a considerable proportion (½ to ¾ per cent.) of chloride of sodium, and some earthy salts of succinic acid; also inosite and grape sugar in small amounts. Albumen, if present, is in small amount.

It was long believed or rather hoped, that the chemical composition would be found to differ according to the organ in which the cysts were situated, and thus afford valuable assistance in diagnosis. This hope was, however, doomed to disappointment. In the case reported by Hayem and Graux (*Progrès Méd.*, No. 19, 1874), in which the echinococcus vesicle clogged the ductus communis choledochus, causing attacks resembling hepatic colic, chemical investigation showed the contents to be of a greenish-yellow color, slightly alkaline, and of a specific gravity of 1.020. It consisted of 97.9 per cent. water, 0.18 per cent. mucus, 0.4 per cent. albumen, 0.58 per cent. chloride of sodium, 0.7 per cent. sulphates, soluble and insoluble carbonates, extractives and coloring matters.

In some cases of liver echinococcus, leucin has been found, while in others it was absent, the investigations being conducted by the same observers.

Succinic acid and grape sugar also fail us as positive aids in diagnosis. Jacobsen found them both in two cases of liver echinococcus and failed to find them in others. Wilde found both these substances in a splenic and in a pulmonary case.

Habran's claim that the so-called hæmatoidin crystals have never been found in any echinococcus cysts except those of the liver and bile-passages, has not yet been disproved, and is worthy, if not of credence, at least of further investigation.

Chemical examination may also be of service in the diagnosis of cysts connected with the kidney as the characteristic urinary constituents have been found in no others. Kidney echinococci, too, are the only ones in which any considerable amount of albumen has been found, the only exception to this being that of repeatedly tapped cysts.

It will be seen from what has been stated, that, although the chemistry of this fluid is tolerably well understood, there is no ingredient which can be positively and absolutely relied upon in the formation of a diagnosis. In the absence of any pathognomonic ingredient, chemical must rank secondary to microscopic examination in the diagnosis of this disease.

Dr. Walter S. Christopher remarked that the chemistry of echinococcus is rather limited. The fluid itself when uncontaminated with the products of inflammation, is usually colorless, but marked by a slight opalescence. It is neutral in reaction and has a specific gravity varying from 1.006 to 1.015. Albumen, when present at all, exists only in small quantity. Sugar is often present, and inosit frequently forms as much as 1 per cent. of the total weight of the fluid. There are also found traces of urea, kreatin, and succinic acid, besides a considerable quantity of chlorides. Of the ingredients present, two are of special importance because of the aid they lend to diagnosis. These two are inosit and succinic acid, Inosit, the so-called muscle sugar, is found in certain of the normal fluids of the body, but in none which ever collect in such large quantity as to produce a cyst. The same may be said of succinic acid, except that it is occasionally found in hydrocele fluid and in the fluid of hydrocephalus, but such collections of fluid could hardly be confounded with an echinococcus cyst. It is somewhat unfortunate, however, that the tests for inosit are such as cannot be applied at the bedside, or, as a rule, by the busy physician. To determine the presence of inosit, it is necessary to separate it from the fluid, and apply the tests directly to the pure sugar. The method of collecting the inosit and applying the test for its presence was then described in detail.

Succinic acid, he continued, is less difficult of recognition than inosit, but it is not so often present. A flocculent brown precipitate is thrown down on the addition of a ferric salt. This is readily distinguished from ferric hydrate by the absence of a decided alkaline reaction, and from basic ferric benzoate by the failure of mineral acids to precipitate succinic acid. The importance of detecting inosit and succinic acid in a fluid supposed to be echinococcic should not be underestimated. While their absence would not prove that the fluid was not from an echinococcus cyst, their presence certainly would prove that it was. And when we consider the other infrequent occurrence of hooklets, and their difficulty of recognition when found, the value of succinic acid and inosit is not less than the classical sign itself.

THE PATHOLOGY OF ECHINOCOCCUS.

Dr. E. W. Walker reviewed briefly the morbid anatomy of the disease. The echinococcus after it has reached the liver or other organ develops a cyst, as has been described. From this cyst are developed usually internally, but sometimes externally, secondary, or daughter cysts. When the cysts develop endogenously, or within the mother cyst, we have a large cystic tumor formed and enclosed in a common sheath, but when the growth is exogenous, or outside of the mother cyst, the entire organ may become riddled. The case under consideration is an example of the latter form of growth. The liver, in the specimen presented, had become

almost entirely transformed into a mass of cysts. There were at least twenty-five or twenty-six cysts of large size, and numerous small ones. These cysts contained fluid varying in specific gravity from an almost watery to an almost semisolid consistence. Microscopic examination of the fluid revealed little of importance. Fragments of membranes were seen, broken-down liver cells, fat globules, cholesterine—in fact, an atheromatous collection of material, but no hooklets. The speaker did not find scolices, although Dr. French reported that he had found them. In a specimen which Dr. Whittaker had obtained by aspiration, and submitted to him for examination, the speaker had found two or three rather dubious specimens of hooklets, too uncertain in their appearance to permit him to make a positive diagnosis from the specimen before operative measures had been undertaken.

Dr. James M. French remarked that the description given by a former speaker of the microscopic appearances of not only the echinococcus, but also of its capsule, the daughter cysts, and the scolices, had been so complete as to leave little to be said in regard to the microscopic examination of such cases. Speaking of the case under consideration, he said that he had made repeated examinations of fluid taken from different large and small cysts after death, as well as of fluid which he had obtained at the time of the operation. The latter specimen was translucent, of low specific gravity, and of a reddish tinge owing to the admixture of a small quantity of blood from the incision. The microscope revealed only red blood-corpuscles, a few white corpuscles, and numerous inflammatory cells. Of the other specimens examined some were clear and limpid, while others were thick and oily, even of an almost semisolid consistence. In these specimens he had found, in varying numbers, cholesterine crystals, free fat globules, fatty liver cells, fragments of the internal fibrillated membrane of the capsule, and inflammatory corpuscles. Calcareous matter was not present. Free hooklets could not be discovered, nor anything resembling them. In one or two instances, however, he had seen what he thought were unquestionably immature scolices. These were attached to fragments of membrane, and would have escaped recognition but for the row of minute hooklets about the head.

DIAGNOSIS OF ECHINOCOCCUS.

Dr. F. Forchheimer said that one of the first points which come up in this connection is that hydatids are with us an exceedingly rare affection. As will be seen further on, cases are met within which the veriest beginner will be able to make an approximate diagnosis; while, on the other hand, there are those in which the diagnosis is either an impossibility or a brilliant inspiration—if you will, a guess. A practising physician in Iceland will have no more difficulty in recognizing this disease than we would in recognizing a pneumonia; we, on the other hand, would have to give very much more thought to cases than is ordinarily done in practice, in order to take into consideration even the possibility of the existence of an echinococcus in making a differential diagnosis. If we are, then, to arrive at any such diagnosis we must in all cases of fluctuating tumors constantly remind ourselves of the possibility of an existing hydatid, and all our tables of differential diagnosis of fluctuating tumors ought to include this form of tumor. The question of necessity, so far as the welfare of our patients is concerned, of doing all this bears in an altogether different direction, and need not be discussed under this heading.

Given, now, a patient with a tumor, the question that arises first will be for us to determine why this tumor can be looked upon as hydatid. To answer this question the patient must be questioned, he himself examamined, and lastly, the tumor most carefully examined. As to the patient, we will find that sex has no predisposing influence—that age, however, is to be taken into very great consideration. The great majority of cases occur between the twentieth and the fortieth years of life. According to Davaine, there are but two non-Icelandic cases on record in children under ten years of age, one, very doubtful, of Cruveilhier in a child twelve days old, and another by Bodson in a girl of four years. Charcot has reported a case in a man of eighty-one, and Monod in a patient of sixty-seven years. The appearance of the patient may or may not be of importance. As a rule, it is not; the presence of a tumor is all that has inconvenienced the patient in the case that has here been presented. He came to his physician apparently a well man; looking well, feeling well, having had no fever, simply possessed of a tumor, or having some function interfered with by its presence. Sometimes, depending upon the location of the tumor or the processes that have been going on within it, the picture is altogether a different one. Pain, fever, emaciation, cachexia, or local symptoms, with all that these may imply, and the patient a most undoubted wreck. With regard to pain, the statements that come to us from those who have seen the greatest number of cases vary very much. Nearly all the authorities that I have been able to consult (Heller, Davaine, Cobbold) claim that the absence of pain is a characteristic of hydatids, while Finsen, who has seen more cases than nearly all the other observers taken together (245), says most distinctly that pain is complained of in all cases and that long before the tumor can be felt. The fact that the most important contributions to our subject have been made by men most interested in the biological aspect of the question must not be overlooked; it would seem more rational, from a clinical standpoint, to suppose that a tumor would produce some pain even if it is not sufficiently appreciated by the physician, as Bamberger says in his classical work on *Diseases of the Chylopoietic Organs:* "Hydatids of the liver sometimes arrive at a very great degree of development . . . . in individuals who have never complained of symptoms to be referred to the liver. In others, however, the development is accompanied by more or less intense, undefined, pressing or lancinating pains." The time taken for the development of the tumor or tumors must also be taken into consideration. Hydatids are a very slow growth, taking years for their development (10–15, Davaine).

Coming now to the examination of the tumor, we will find that there are some things that will make our diagnosis a very easy one, while in other cases it will be impossible. The locality of the tumor must be determined precisely; more hydatids are found in the liver than in all the other organs taken together; after this organ comes the lung. The tumor itself is, as a rule, spherical, fluctuating, and dull upon percussion. Its outlines are

smooth; it is elastic, and when examined in a peculiar way gives a sign which is considered almost pathognomonic by most authors. The latter is called the hydatid fremitus (frémissement) of Brianzon, not Piorry, for the former has undoubted right to priority. The French authorities are extremely particular concerning the method by which this symptom is to be detected. Brianzon states that "the tumor must be grasped as firmly and exactly as possible, exercising a slight pressure, and with the other hand a sharp and rapid blow is to be given." Others are still more explicit. The sensation perceived by the hand grasping the tumor is described in various ways; a trembling as of jelly; the sensation produced when touching a piano-string of low pitch while striking the key of the note itself, etc. If we look at the physical basis of this phenomenon, we find that when a fluid is contained within elastic walls and is set into vibration the fremitus is produced. As Skoda puts it, "If percussion is made upon a stomach filled with water, and held in air, we will have the clearest conception of what Piorry understands by the hydatid tone." Davaine practically admits this explanation. One can hardly be allowed to doubt the opinion of Skoda on so simple a matter, and it is therefore but logical to assume that the fremitus is not absolutely characteristic of hydatids. Any collection of fluid under the above-mentioned conditions, when struck and examined in the way described, will give the hydatid fremitus. The discussion of its occurrence in acephalocysts, therefore, is one that is upon a wrong basis—the existence or non-existence of buds being a secondary consideration, the relation of fluid to the wall and the elasticity of the latter, being the primary one. If we look to our authorities, we find Davaine, indeed, the whole French school, putting their trust absolutely upon this one sign. Heller states that it is "almost pathognomonic;" Cobbold says that "it scarcely differs from the ordinary impulse communicated by fluid matter within any other kind of tumor;" Bamberger has found it in ascites and ovarian tumors, and therefore conceives it not at all characteristic. Besides, Frerichs, who seems to believe in the sign, says that he could not detect it in more than half his observations. And lastly, the tumor frequently is in such a locality that it cannot be examined for this symptom. Taken all in all, then, the hydatid fremitus is going the way of all other pathognomonic signs.

When the modern physician deals with a tumor concerning the contents of which he is in the dark, he proceeds to investigate it with an exploring needle, hypodermatic syringe, or aspirator. By means of one of these methods he frequently obtains results most valuable to his diagnosis. When in one case there is enough fluid to be drawn off, this must be examined most carefully. It will be found to be a clear, sometimes yellowish, neutral or slightly alkaline fluid, of a specific gravity varying from 1.007 to 1.019. This fluid does not, as a rule, contain any albumen, but is very rich in sodium chloride. Other substances are found, as sodium and potassium succinate, leucin, inosit, grape sugar, and hæmatoidin. Of all these, the absence of albumen and the presence of sodium chloride in large quantities (as high as 0.84 per cent., Jacobsen, Heller) seem most characteristic. Of these two signs, the sodium chloride is the most constant, albumen being frequently found—always after the tumor has been frequently tapped. It would be very convenient if the presence of succinic acid could be relied upon as a characteristic test. According to Hoppe-Seyler, succinic acid is found in the juice of various organs, spleen, thymus and thyroid glands, in the fluids from hydrocephalus and hydrocele, the blood, and possibly in the urine. Any possible mistake between the parenchymatous fluid of the organs mentioned above could be avoided by noting the quantity, color, and the chemical reactions of the fluid, and, above all, by the location of the tumor. The same can be said for hydrocephalus and hydrocele, and it would therefore seem that we had found in the presence of succinic acid a reliable test. Especially can this be relied upon because it is a test which can be executed by the beginner—the addition of a ferric salt (ferric chloride) produces a brown, insoluble precipitate in fluids containing succinic acid. If albumen be present, absolute alcohol will precipitate both it and the acid; with the coagulation of albumen comes down the succinic acid—after filtering off the fluid the acid is readily dissolved in water, and the test can then be applied. If we find the acid then, we can be sure that we are dealing with hydatid fluid. Unfortunately, it is not found in all cases, probably not in the majority of the cases. All the other substances found in the tumor are determined more by its locality than by its character, and are therefore of comparatively little importance because they may be found in so many fluids. After the chemical comes the microscopic examination. Here we come to evidence that points with absolute certainty to the diagnosis. The presence of the ectoderm of buds or of hooklets is absolute certainty of the existence of a hydatid. These have already been so well described that I will not again go over the subject. It may happen, however, that either on account of the rupture of the tumor, the extreme smallness of the instrument, or the inaccessibility of the tumor, that neither of these can be found. In such a case we must rely upon the preceding signs. If they are all absent, a diagnosis naturally becomes an impossibility. This must happen, and perhaps quite frequently. A tumor the presence of which is not observed by the patient will certainly not receive much attention at the hands of the physician. Symptoms produced by the presence of a tumor, the latter being inaccessible, will be thoroughly examined into, the nature of the tumor being as obscure as its locality, unless other tumors be observed in different parts of the body—for us, especially the liver and lungs. When the tumor itself can be examined there can arise a doubt only in case it has undergone ulceration, suppuration, or the so-called tubercular degeneration. In the latter instance, especially in echinococcus multilocularis, the fluid may not show any of the characteristics of hydatid fluid. Under ordinary circumstances one or other of the signs just described will be found.

(*To be continued.*)

CORRESPONDENCE.

ERROR IN STATEMENT OF RESULTS OF BATTEY'S AND TAIT'S OPERATIONS.

To the Editor of The Medical News,

Sir: In your issue of July 3d, Mr. Tait says: "I brought from a distance of forty miles the patient whom he says died after the operation on August 1, 1872," etc.

This is another "slip of the pen." At no time have I said that this patient *died*. The statement in my paper, at the Congress, was a simple repetition of the assertion of Mr. Tait himself in the *British Medical Journal*. It was written some time before and ought to have been omitted. Respectfully yours,

ROBERT BATTEY.

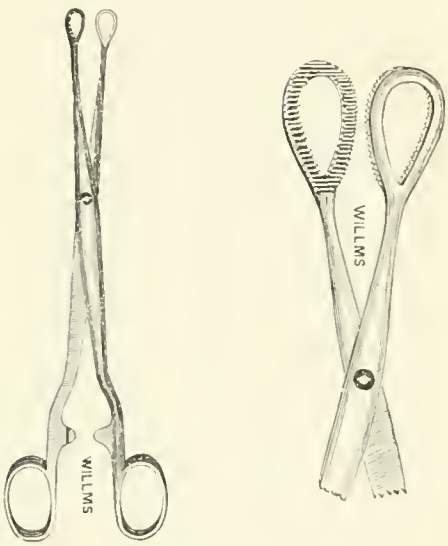
ROME, GA., July 10, 1886.

NEW INVENTIONS.

COMBINED SPONGE AND PLACENTAL FORCEPS, AND CURETTES, ETC.

BY ROBERT T. WILSON, M.D.,

ASSISTANT SURGEON TO THE HOSPITAL FOR THE WOMEN OF MARYLAND, BALTIMORE, MD.



In these cuts is shown a useful instrument calculated to be of service in several ways, namely:

1st. As a sponge forceps.

2d. As a placental forceps, after an abortion, where the membranes are retained.

3d. By taking the instrument apart, one has two curettes, which may be used when a dull curette of their size is required.

4th. As a forceps to be used in the removal of a stone from the bladder.

5th. As a forceps for holding the tongue (an instrument an anæsthetist sometimes wants).

No doubt the forceps will be found to be useful in more ways than those here mentioned. They were made for me, in February, 1885, by Chas. Willms & Co.

I append an opinion in regard to them by my friend, E. C. Carter, M.D., Assistant Surgeon U. S. A., to whom I presented a pair last year:

"I had an opportunity to try your forceps in a case of abortion, criminally induced, with retention of membranes. The forceps did the work required of them perfectly, and I am convinced the woman, a Mexican, would have died if I had not had them.

"Indeed I regard the forceps as a valuable addition to my armamentarium."

NEWS ITEMS.

CONFERENCE OF M. GRANCHER ON THE PROPHYLAXIS OF HYDROPHOBIA.—On June 22, 1886, M. Grancher, the collaborator of M. Pasteur, presented, for the first time, the clinical history of the patients treated for hydrophobia by vaccination. The persons bitten and vaccinated were grouped in three classes:

1. Those bitten by a dog of which the nervous system was sent to Pasteur's laboratory, inoculated in rabbits, and caused death of the latter by hydrophobia; or those who had been bitten by a dog the bite of which had caused death by hydrophobia in other animals or man.

2. Those bitten by a dog which before or after death had been examined and declared rabid by a veterinarian.

3. Those bitten by a mad dog which had escaped observation.

The statistics extend to April 22, 1886.

The total of the three categories includes 1335 patients. Elaborate and rigorous statistics prepared by M. Leblanc, Member of the Academy of Medicine and Veterinarian to the city of Paris, show that of 100 non-vaccinated persons bitten by rabid animals 16 die.

In the first group above mentioned there were 96 patients, of which 1 died, a mortality of 1.04 per cent.

In the second series are 644 subjects and 3 deaths, a mortality of 0.46 per cent., or for the two series, of 0.75 per cent.

In the third series are 232 cases, which are here disregarded.

The mortality among patients bitten on exposed surfaces (the face and hands) was in the first group 54, with 1 death, mortality 1.8 per cent.; in the second group, 400 with 3 deaths, mortality 0.75 per cent. M. Brouardel, in examining the statistics of the Council of Hygiene from 1862 to 1872, finds that in non-vaccinated persons bitten on exposed surfaces, the mortality is 80 per cent.

In addition, M. Pasteur has vaccinated 48 persons bitten by mad wolves; of these 7 have died, giving a mortality of 14 per cent. M. Brouardel has shown that non-vaccinated individuals similarly bitten present a mortality of 66.5 per cent.

If the efficacy of the rabic vaccine be compared with that of the *charbon* vaccine and the Jennerian lymph, it is found that the three agents have practically the same value.

Before the introduction of the Jennerian vaccination, out of 1000 smallpox patients, 500 died, while after its introduction but 23 out of 1000 vaccinated persons succumbed. The value of Jennerian vaccine is, therefore, $500 : 23 = 21.7$.

Similarly for *charbon*. Before the use of Pasteur's vaccine the mortality was 120 per 1000, while at present out of 1000 vaccinated animals but 5 die. The value of the *charbon* vaccine is, therefore $120 : 5 = 24$.

In rabies, before the method of vaccination, the mortality was 160 per 1000, while after vaccination the deaths were 7 per 1000. The value of the antirabic vaccine is, therefore, $160 : 7 = 22.85$.

The lecture was received with enthusiasm, and several hundred persons were unable to obtain standing

room. It will probably be repeated in the great amphitheatre of the École de Médecine.

PROFESSOR SEMMOLA, of Naples, well known for his numerous scientific researches, has just been honored by official appointment as Senator of the Kingdom of Italy.

GERMAN VACCINE COMMISSION.—The Chancellor has convened a Commission to consider the formation of a council which shall give authoritative instruction in the methods of securing, preserving, and transporting animal lymph. The Commission, under the direction of Dr. Kohler, consists of Drs. Koch, Gaffky, Schönfeld, Grossheim, Schulz, Pissin, and Hausburg, all of Berlin; and of Risel, of Halle, Kranz, of Munich, Chalybäus, of Dresden, v. Koch, of Stuttgart, Arnsperger, of Karlsruhe, Fischer, of Pforzheim, Reissner, of Darmstadt, Pfeiffer, of Weimar, and Krieger, of Strasburg.

CREMATION ON LONG ISLAND.—Since December 4, 1885, there have been forty-five bodies cremated at the Crematory of the New York Society, Fresh Pond, L. I.

MEDICAL PROGRESS IN CHICAGO.—Dr. Gregory writes to the *Medical Press*, of Western New York, his impressions on visiting Chicago after a six years' absence. He says: "In the six years last past, the medical element of Chicago has developed beyond the stage of personal gain, and reached that of public benefit. Physicians there are not now telling of the number of prescriptions written in a day, so much as they are detailing anomalous conditions met with. To be sure, even a professional man, breathing a truly professional spirit, cannot live in Chicago without becoming imbued with a business fervor; consequently nearly all physicians have a down-town office as well as one at their residence. This peculiarity is very noticeable, as sometimes as many as twenty-five physicians are grouped in down-town offices over a drug-store. St. Louis is the only other city where this concentration of physicians' offices down town and over drug-stores occurs so conspicuously. While in this feature Chicago differs from Eastern medical centres, she now resembles them in multiplied agencies through which physicians render the public gratuitous service. Six medical societies and an unknown number of clubs are maintained, and eight medical journals are published in the city. With this mass of public work, and the large number of men thus engaged, it must be evident that a far different professional spirit would be engendered than without such agencies. Chicago must therefore be recognized as the medical centre of the West. Undoubtedly one of the agencies tending to produce this result is the State medical law, for in marked contrast to its previous condition is the present absence of charlatan advertisers and nostrum doctors."

A BELGIAN PRIZE TAKEN BY AN AMERICAN PHYSICIAN.—The competition instituted by L'Académie Royale de Médecine de Belgique in 1881, and continued through 1883, is closed, and the report of the Commission of the Académie is made known. The question submitted was: "To Elucidate by Clinical Facts and by Experiments the Pathogeny and the Therapeutics of the Diseases of the Nervous Centres, and especially of Epilepsy." A number of memoirs were submitted, which were entered by European authors of preëminent rank in this department of research. The honors of the competition have, however, been awarded to an American physician, Dr. George T. Stevens, of New York. His memoir is the only one selected by the Royal Academy for publication, and the only one for which an award was made.

THE WOMAN'S MEDICAL COLLEGE OF NEW YORK.—Dr. H. M. Silver has been appointed Professor of Surgery in the Woman's Medical College of New York, and Dr. W. Meyer, Clinical Professor of the same branch.

SCIENTIFIC JOURNALS IN JAPAN.—A paragraph in *Nature* states that there are thirty-seven periodicals published in Japan, devoted to matters connected with education; of this number, seven are medical papers, with a monthly circulation of 13,514. There are nine papers relating to sanitary matters, and two to pharmacy. There are also nine other papers devoted to other branches of science; and no fewer than twenty-nine papers, with a circulation of over 70,000, engaged in disseminating a knowledge of popular science.

MORTALITY AMONG MEDICAL MEN DURING THE TYPHUS EPIDEMIC IN MOSCOW.—The typhus epidemic in Moscow, which is now, it seems, on the wane, has played great havoc in the ranks of the profession, no less than five junior police surgeons having already died. Most of them were without private means, and left their families entirely without provision. Five more surgeons have been attacked by the disease, and it is hoped that they may recover.

REGAL ANTISEPTICS.—The King of Servia, according to the journals, has issued the following proclamation: "Whereas it is irrefutably proved by science that the so-called antiseptic treatment of wounds yields more beneficial results than all other methods, we are pleased to order that henceforward the said antiseptic plan of treatment be solely employed in all the hospitals of our kingdom, and that corrosive sublimate and iodoform be used until our further disposition."

EARLY DISCOVERY OF COCAINE.—It is generally supposed that Niemann, a German chemist, was the first to discover cocaine, having isolated it as early as 1859. Dr. Clemente Torretti, late professor of chemistry and pharmacology at the University of La Paz (Bolivia), now writes to a South American journal that he has found irrefutable proofs, showing that in 1857 a Mr. Enrique Pizzi, his (Dr. Torretti's) predecessor in La Paz, succeeded in isolating the alkaloid of the coca-leaf, having been encouraged to make experiments on the coca leaves by Mr. Tschudi, the celebrated Austrian explorer, and Dr. Aquila Ried, a well-known personage in Valparaiso. Dr. Torretti adds that his assertion is not founded on documentary evidence only, but that he has actually found specimens of the cocaine manufactured by Pizzi in 1857.

THE AMERICAN RHINOLOGICAL ASSOCIATION will hold its fourth annual meeting at St. Louis, Mo., on the 6th of October next.

DEFECTIVE DRAINAGE.—A London builder was recently fined five pounds for allowing a dwelling to be tenanted before a certificate had been granted showing that the house was fit for habitation. Another builder was fined forty shillings for the same offence. The defects related chiefly to the water-supply, drainage, and ventilation.

PEDESTRIAN INSTRUCTION.—On the 21st of June there was opened on Glen Island, in Long Island Sound, near new Rochelle, a "Military Camp of Instruction in Marching," under the superintendence of the veteran pedestrian, Edward Payson Weston. The competitors, who are made up of members of the various militia regiments, are each to walk twelve hours a day for six days, carrying forty and a half pounds in the way of knapsacks and accoutrements, and the camp will be continued for nine weeks. On the opening day, an address was delivered by Prof. R. Ogden Doremus, in which he referred to Weston as the father of walking in this country, stating that since 1867 he had walked 63,500 miles, and that Dr. Richardson, who examined him in London, pronounced him the healthiest man he had ever examined. He concluded as follows: "I would advise all, if they desire good health, to sweat daily as the result of physical exercise. Gentlemen, I look upon this camp as the initiative step toward splendid results in our country."

A NEW DENTAL JOURNAL.—There has just been published in Breslau the first number of the *Journal für Zahnheilkunde*, which is the official organ of the "German Association of Dentists graduated in America."

PURCHASE OF NEW GROUND BY THE MANAGERS OF THE PENNSYLVANIA HOSPITAL.—The Pennsylvania Hospital has purchased about five hundred acres of land at Newtown Square, Delaware County, to be used, for the present, as a "convalescents' retreat," and ultimately as a new site for the hospital for the insane. The land cost from $200 to $300 per acre, and comprises four of the best farms in the county. It is reported that the buildings now on the grounds will be utilized for homes or retreats for the convalescent patients of the Hospital for the Insane in West Philadelphia, and those of the department of sick and wounded, at Eighth and Spruce Streets. It is thought that the change of air will hasten the recovery of these patients, while, at the same time, it will make room for new patients and somewhat relieve the present crowded condition of the various wards. No building operations will be begun on the new grounds until next year, as the time of the contemplated removal of the Hospital for the Insane has not been decided upon, but it will not be for some time yet. Newton Square is about five miles south of Bryn Mawr, and about an equal distance northeast from Media.

THE HYGIENE OF THEATRES.—Given a spacious theatre, crowded during an evening performance for a period of hours, what is the difference of the effects on its atmosphere produced by the electric light or by gas, particularly as to the temperature and the generation of carbonic acid? Such is the problem which Dr. P. Renk, Professor of Hygiene at Munich, has just set himself to solve. Taking the Theatre Royal of that city, which is lighted by 1400 lamps on the Edison system, he tested the two kinds of illuminants, with the following results: During a representation which lasted from 5.30 P. M., to 10.15 P. M., and was witnessed by 1790 people, he found that while the rise in temperature in the pit was 11.1° C. with gas, it was only 7.7° C. with the electric light, and that in the upper gallery it was 10.7° with the former, and not more than 7.4° with the latter. As to the increase in the production of carbonic acid, the results were equally important. In the pit it was as 2176 with gas to 1221 with the electric light, and in the upper gallery as 2855 with the first to 1430 only with the second.

AUSTRIUM: A NEW ELEMENT.—Among the papers of the late Dr. Linnemann, Professor of Chemistry in the University of Prague, has been found a communication addressed to the Royal Academy, and bearing the title, "Austrium, a new metallic element." It describes a new metallic element obtained by the deceased from arthite from Arendal, having a spectrum with two characteristic lines in the violet, one of which is fairly coincident with an unidentified line in Angström's atlas. It is stated that the paper will be published in the transactions of the Academy.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM JULY 13 TO JULY 19, 1886.

GIBSON, JOSEPH R., *Major and Surgeon.*—Granted leave of absence for three months, to take effect August 1.—*S. O. 158, A. G. O.*, July 10, 1886.

BENNETT, RICHARD, *Captain and Assistant Surgeon.*—Leave of absence extended six months, on Surgeon's certificate of disability.—*S. O. 162, A. G. O.*, July 15, 1886.

GARDNER, EDWIN F., *Captain and Assistant Surgeon.*—Granted leave of absence for two months.—*S. O. 158, A. G. O.*, July 10, 1886.

KANE, J. J., *Captain and Assistant Surgeon.*—Ordered from Fort Ringgold, Texas, to Fort Hancock, Texas.—*S. O. 85, Department of Texas*, July 13, 1886.

CARTER, WM. F., *Captain and Assistant Surgeon.*—Ordered from Fort Concho, Texas, to Fort Ringgold, Texas.—*S. O. 85, Department of Texas*, July 13, 1886.

OWEN, WM. O., *First Lieutenant and Assistant Surgeon.*—Ordered for duty at Fort Schuyler, New York Harbor.—*S. O. 84, Division of the Atlantic*, July 15, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE NAVY, FOR THE WEEK ENDING JULY 18, 1886.

WENTWORTH, A. R., *Assistant Surgeon.*—Detached from the U. S. Steamer "Brooklyn" and wait orders.

NORTON, OLIVER D., *Assistant Surgeon.*—Detached from the U. S. Steamer "Minnesota," and to the U. S. Steamer "Brooklyn."

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING JULY 17, 1886.

WHITE, J. H., *Assistant Surgeon.*—Granted leave of absence for thirty days, July 12, 1886.

PETTUS, W. J., *Assistant Surgeon.*—When relieved at Charleston, S. C., to proceed to Savannah, Ga., for temporary duty, July 9, 1886.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course, not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1008 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

THE CARDIAC COMPLICATIONS OF BRIGHT'S DISEASE.[1]

BY JAMES T. WHITTAKER, M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE AND OF CLINICAL MEDICINE IN THE MEDICAL COLLEGE OF OHIO, CINCINNATI.

THE heart and the kidneys stand in relation to each other, in the machinery of man, as the feeding or force-pump, and the escape or waste-water pipe. Disease of either one of these organs is therefore, of necessity, attended, sooner or later, with disease of the other.

In this relation the disease process may begin in the heart. In the general interference with the circulation which then ensues, stasis in the kidneys is revealed by a diminution in the quantity of urine, which becomes dark and heavy, shows thick deposits of urates, and later albumen, hyaline cylinders, and blood corpuscles. Both acute and chronic nephritis may thus develop from endocarditis or myocarditis.

Or, the kidneys may be affected secondarily by becoming the repositories of emboli, benign or malignant, with hemorrhagic infarctions, and so-called metastatic abscesses, which reveal themselves by the sudden appearance of hematuria, by suppression of urine, or may remain latent to be discovered only upon autopsy.

Next, both heart and kidneys may be affected simultaneously under the operation of the same cause, as by alcoholism, syphilis, or gout, as well as in the general wreck of the so-called arterio capillary sclerosis.

Lastly, the disease process begins in the kidneys and leads consecutively to disease of the heart, to pericarditis, more rarely to endocarditis, but most especially to hypertrophy of the left ventricle, a complication universally observed ever since its presence was first pointed out by Bright, though its significance has received proper interpretation only within recent years.

This curious condition which we know now to be compensatory, hence, to be favored and sustained in every way, is the sole cardiac complication which the limit of time allotted will permit me to discuss.

Hypertrophy of the left ventricle belongs to Bright's disease as much as do dropsy, albuminuria, and uræmia. It is one of the cardinal symptoms of the disease, but it rises above the other signs, rises, in fact, to physiological dignity in that it expresses an effort to overcome or neutralize the main effects of the disease.

It should be remarked, in the first place, that hypertrophy of the left ventricle is present in every case of chronic nephritis. The view that it occurs only in renal cirrhosis, in the so-called granular, contracted, or atrophied form of the disease, and is limited to this form, has been shown to be entirely erroneous. There is no such thing as a chronic nephritis without hypertrophy of the heart, unless, indeed, in the fortunately few cases where the patient is too feeble to develop an increase of tissue in any organ. Apparent but not real exception is also offered in the last stages of Bright's disease, when the hypertrophy has finally given place to dilatation as a last link in the chain of the disease process. The statement of Bartel's that any hypertrophy of the heart without valve lesion to account for it, ought to direct attention to renal cirrhosis should be modified to read, should excite suspicion of Bright's disease in general. A hard, wiry pulse, in the absence of fever or of any superficial evident disease, is enough, of itself, to excite this suspicion in the mind of the alert practitioner, and the sign is all the more valuable in that it shows itself early in the insidious course of this disease, months and sometimes years before nervous symptoms, dropsy, or failure of nutrition suggest the nature of the affection. For the increase in the impact of the heart is frequently to be observed in the course of two to four weeks from the inception of the disease, when this period may be determined, at which time it is already demonstrable on autopsy. It develops quickest and most completely in the healthy and robust.

Theories only prevail as yet regarding the cause of it. Bright who, as remarked, discovered it, but who could not at that time realize the importance of it, adopted the conservative view that it was caused either by the irregular and unusual irritation of the heart produced by the changed condition of the blood, or by the call upon the heart for increased activity to force the blood through distant contracted bloodvessels. Bright thus announced the two theories, chemical and mechanical, which still find advocates in the present day. In 1856, Traube published his support of the mechanical view in a paper that has been widely quoted ever since. He noticed it in connection only with the contracted kidney, and made it diagnostic of this form of Bright's disease. He derived it from the diminution in the quantity of blood flowing through the kidney, diminution also in the quantity of urine excreted, with the consequent accumulation of fluid in the aortic system and elevation of blood pressure. Traube established the theory of compensation.

In refutation of this view, it has been shown, first, that after extirpation of an entire kidney or the amputation of an entire member, with the consequent ablation of a much greater number of capillaries, whole systems of capillaries in fact, hypertrophy of the heart does not ensue, as the blood finds escape to other vessels, in the case of the kidney to the other kidney, which enlarges to do double duty;

[1] Read before the Ohio State Medical Society, June 3, 1886.

second, that hypertrophy develops also in cases where there is no atrophy of the kidney substance, as in chronic parenchymatous nephritis; third, that there is no diminution, but, on the contrary, an increase in the excretion of urine in the granulated kidney; fourth, that ligation of the ureters alone is followed by this hypertrophy.

But these objections have been more or less successfully met thus: first, that the cases of extirpation of the kidney have not been watched long enough to observe gradual and remote effects upon the heart. Grawitz and Israel in their experiments upon rabbits, and Lewinsky in his experiments upon dogs, in securing not sudden but gradual occlusion of the renal arteries, such as occurs in disease, invariably saw degeneration of the kidney structure ensue with hypertrophy of the left ventricle of the heart; second, that while this hypertrophy does follow parenchymatous nephritis, there is none the less occlusion in this form of Bright's disease; third, that while the quantity of water is increased in renal cirrhosis, the blood-pressure is undoubtedly raised in the aorta to produce the increase in the water excreted; and fourth, that ligation of the ureters produces disease of the kidneys leading at times to obstruction of the circulation, and when this obstruction does not occur, as in cases of pyelitis, no hypertrophy of the heart ensues.

From this summary of the evidence, it must be admitted that the bulk of testimony favors the mechanical theory and puts this hypertrophy in the same position as that which ensues upon valvular defects, or as that which occurs in the right ventricle in consequence of any block in the lungs. It is difficult to subscribe to the chemical theory of hypertrophy as advocated recently by Frerichs and Senator in the face of the fact that uræmia or retention of any toxic elements of the urine from other cause, as from cystitis, pyelitis, etc., is not attended by hypertrophy of the heart. There is abundant analogy in the body for hypertrophy in face of obstruction, that is, hypertrophy and hyperplasia, increase in size from increase of activity, but none for increase in anatomical elements under the action of a poison.

Inasmuch as the hypertrophy is preceded by a rise in tension in the aortic system, the pulse shows changes before the heart. It becomes, as stated, full and hard. It is at this time also slow, and while its frequency is increased with the development of the ventricular hypertrophy, it remains full and hard until the force of the heart finally begins to flag. The pulse now becomes rapid, feeble, and in the last stages flutters, so that most cases, unrecognized hitherto, are regarded as cases of simple heart disease. Then, inasmuch as the last stages of primary heart disease involve the kidneys with consecutive lesions, it is at times impossible to declare the order or sequence of the disease process, though this fact has at this time little or no clinical value, as the subsequent duration of life is short. The recognition of this relation between the heart and kidneys gives a satisfactory explanation to the popular belief that Bright's disease is on the increase in modern times, for many cases of primary Bright's disease were formerly regarded as cases of heart disease.

Of far higher value is the early recognition of Bright's disease before extensive lesions in the kidney have been produced, for it is only at this time that the disease process may be checked or cured.

Where the suspicions of the physician are once excited the diagnosis of Bright's disease is usually easy enough. The practitioner who makes it a habit to test the urine, if only by heat, in every case of chronic disease is rarely led astray. But the observation must be made with constant knowledge of the fact that while the presence of albumen in a general way denotes disease, the absence of it by no means of necessity excludes it, as it is exactly in the cases of renal cirrhosis in which for days at a time not a trace of albumen may show in the urine, healthy urine being voided from regions of the kidney entirely unaffected by disease, while the diseased parts are completely blocked.

In all these cases, as well as in those where the patient presents himself with a diagnosis of heart disease when no valve-lesion can be found to account for it, the kidneys should be suspected and scrutinized for symptoms immediate and remote.

Hypertrophy of the left ventricle reveals itself first by a slight deviation of the apex to the left. Obesity, or, later, anasarca or hydrops, may conceal or obscure the increase in size, but nothing may conceal or obscure the dislocation of the apex beat. A heart which shows its apicial stroke below or to the left of the nipple is either enlarged or out of place. Various extrinsic causes may also produce the condition, but they may be more or less eliminated in the history of the case. At least a pleuritic effusion or a tuberculous change in the lung-tissue, the most common extrinsic causes, should not long embarrass a diagnosis. Hypertrophy from endocarditis would distinguish itself by a characteristic bruit, as well as by accentuation of unaffected valves.

The increase in the size of the heart manifests itself by dulness, which extends to the left of the mammary line. In a pronounced case this increased dulness is readily recognized, but when slight in degree it is not so valuable as deviation of the apex. Perhaps it is not unfair to say that moderate hypertrophy of the heart makes itself manifest to most of us by the increased area, not of dulness, but of impact to the hand laid flat upon the surface of the chest, or to the face in auscultation of cardiac sounds.

The next most valuable sign of this hypertrophy is accentuation of the second aortic tone. The reason of this is obvious. The hypertrophied ventricle forces its blood into the aorta which is already distended, and the closure of the aortic valves follows under pressure with a quick short click—in short, with a distinct accentuation audible all over the heart, but in greatest intensity at the base, on the right of the sternum at the junction of the second rib. Now just as accentuation of the pulmonic valve sound, which is heard in its maximum intensity on the left of the sternum, points to hypertrophy of the right ventricle from mitral regurgitation due chiefly to endocarditis, does accentuation of the aortic sound point to hypertrophy of the left ventricle due chiefly to Bright's disease.

These four signs, increased tension of the radial

artery, dislocation of the apex to the left, increased dulness and impact, and accentuation of the second aortic tone, constitute the phenomena of this principal cardiac complication of Bright's disease. The importance of them becomes evident with the observation that they all exist at a time when there may be no subjective symptoms pointing to the heart.

But the compensation of this hypertrophy is not always exact. It may reach extremes in both directions, of excess and of failure. In otherwise healthy, vigorous subjects, more especially in those leading indolent or sedentary lives, or in children with abundant nutrition, it reaches a degree at times superior to the demand. Attacks of violent palpitation may then ensue with audible throbbing and marked increase of impact which makes itself manifest in yielding chest-walls as visible elevations or prominent bulgings of the surface. Hyperæmia of the brain occurs in these cases with intense headaches, and vertigo entirely independent of uræmia, and epistaxis may be frequent and severe. Strümpell reports two cases of fatal nose-bleed from this cause.

On the other hand, in constitutions enfeebled by original construction or by acquired disease, the cardiac hypertrophy may fail to develop, and in all cases sooner or later it must fall short under the gradually increasing demands. The nice compensation which has hitherto sufficed to obviate the main danger of nephritis, the retention or non-excretion of sufficient urine, becomes disturbed, and the signs of accumulation of toxic elements speedily ensue.

The first sign of a flagging heart is noticed in the pulse, which loses its hardness to become frequent and small. The great evil of stasis in the lungs from incomplete emptying of the left ventricle, accumulation in the left auricle and pulmonary veins, is counteracted for a short time by hypertrophy of the right ventricle which now sets in. But it is a work of Sisyphus that is thus thrown upon the right ventricle. It soon yields to the strain, and dilatation is evidenced in the attacks of bronchitis, dyspnœa, asthma, and œdema pulmonum which soon supervene. There is headache from anæmia of the brain, and general dropsy, which commences about the ankles and eyelids, mounts to the genital organs, and, invading the serous sacs, soon puts an end to the scene.

Bright's disease is subject to many accidents, the mention of which is superfluous here; but few of these accidents may occur while the heart is able to compensate the defect in the kidneys. So long as the increase in its size may enable it to force more blood through vessels yet unobstructed in the kidney neither dropsy nor uræmia may ensue. The gradually increasing hypertrophy of the heart is the reserve guard that is brought to bear upon the enemy in front. The successful therapy of Bright's disease calls, therefore, for a close regard of the condition of the heart. When the compensation is excessive, so to speak, the heart should be quieted, above all things, by rest, by the use of the bromides, possibly by an occasional dose of chloral, or, if necessary, by the application of an ice-bag over its walls. Gentle exercise is indicated after the acute explosion of the attack.

But it is the failure that is to be feared more than the excess. Here, above all things, is absolute rest to be secured. Where the means of the patient will permit, nothing is so valuable as a sojourn in a warm and equable climate. I have myself seen several cases of pronounced Bright's disease cured by a winter's stay in Florida or Nassau. For the mass of patients confinement, not only to the house, but to bed, secures, with an equable temperature, the best conservation of the force of the heart. Sooner or later appeal must be made to digitalis. It should be given first in small doses, lest it overstimulate, to be gradually increased according to demand, and discontinued, lest it exhaust—so soon as its effect is apparent upon the heart. The best preparation is known to be the infusion, freshly prepared from the leaves. It should be given to adults in doses varying from a teaspoonful to a tablespoonful, every two or three hours, with knowledge of the fact that it does not begin to show decided effects for twelve hours, and continues as long after its administration is stopped. Should it be continued long after its full effect is produced upon the pulse, the heart is tetanized, and the patient falls into collapse. Its diuretic action is much increased by the addition of the acetate of potash, but the infusion does not keep so well with this addition.

It is indeed a fatal mistake to administer digitalis while the heart is still adequate to the work of compensation. Neither uræmia nor albuminuria, of necessity, calls for digitalis. Dropsy is, in general, the best indication, because dropsy indicates inadequate compensation on the part of the heart, which is also, and often in the absence of dropsy, manifest in the condition of the pulse. Other symptoms of Bright's disease are infinitely better treated by appeal to the skin, wherein prolonged hot baths outrank all other remedies.

When the heart has fully responded to digitalis, and its further administration is contraindicated by the state of the pulse, tonic effects are best sustained by arsenic and iron; and when, finally, the heart no longer responds to digitalis, resort must be had for relief of symptoms to alcohol and morphia. But this day may be long delayed by a vigilant supervision of the heart, which, next to the secretion directly from the kidneys, most distinctly gauges the stage of the disease.

SOME CLINICAL FACTS ILLUSTRATED BY:

1. A CASE OF ABSCESS OF THE LIVER AND ULCER OF THE STOMACH.
2. A CASE OF ULCERATIVE ENDOCARDITIS.[1]

By E. T. BRUEN, M.D.,
ASSISTANT PROFESSOR OF PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA.

There are certain diseases in which the conformity to the classical type is so uniform that a special description is superfluous, but there are others in which the diagnosis is rather made up by exclusion based upon an estimate of the rational symptoms, the physical signs, and the etiological relations. Cases of disease belonging to this class will always possess an

[1] Read before the Clinical Society of Philadelphia, March, 1886.

interest when considered independently of others, until their clinical delineation shall become as distinct as the differences which define enteric from typhus fever.

There are certain morbid processes which affect different organs, yet which possess clinical symptoms in common which make it reasonable to study their diagnostic features at the same time. As an example, I shall first describe a case of multiple abscess of the liver with perforating ulcer of the stomach. The specimens were taken from the body of Thos. G., a colored man twenty-nine years of age. The liver was very much enlarged, weighing six pounds. The entire right lobe was filled with small, round, abscess cavities, some as large as an orange, possessing ragged walls formed of the broken-down hepatic tissue, and containing laudable yellow pus. The peri-hepatic surface beneath the diaphragm was covered with lymph, but no pus. Beneath the left lobe of the liver, but without communicating with the hepatic gland, was found a collection of pus completely encysted by adhesions formed by the mesentery, which enclosed also the posterior wall of the stomach, the head of the pancreas, and the adjacent tissues. Communicating with this abscess cavity was a short sinus which terminated in an ulcer in the upper part of the posterior wall of the stomach, near the lesser curvature and in the middle zone. Without doubt the abscess was a secondary lesion developed after the perforation of the wall of the stomach. The spleen was enlarged, weighing sixteen ounces, but the other abdominal viscera were normal. There was an old cavity in the apex of the left lung with induration of the lower lobes, pleural adhesions, and evidences of recent pericarditis sicca, doubtless excited by the adjacent hepatic inflammatory processes. The pulmonary process had been latent or in stage of arrest prior to the outbreak of the disease in the abdominal organs.

The salient clinical features were that the patient entered the Hospital during the latter part of December, complaining of indisposition, but was discharged at his own request, and returned to his occupation as an hostler. He was readmitted to the wards February 1, 1886. Thus the existing disease must have developed during a period not more than four weeks. When admitted he gave the history of indisposition for the preceding two weeks with nosebleed, a few irregular chills, and slight diarrhœa, with weakness. The temperature on admission was 105°, subsequently ranging as follows:

Feb.	1,	105°	A. M.,	100°	P. M.	Feb.	11,	103°	A. M.,	100°	P. M.
"	2,	95.4	"	104	"	"	12,	102	"	106	"
"	3,	97	"	101	"	"	13,	95	"	105	"
"	4,	95	"	100	"	"	14,	97	"	101	"
"	5,	97	"	100	"	"	15,	99	"	104	"
"	6,	101	"	102.4	"	"	16,	96	"	102.4	"
"	7,	101	"	103	"	"	17,	97	"	97	"
"	8,	101	"	102	"			104			
"	9,	100	"	102	"	"	18,	104	"	96	"
"	10,	101	"	102	"	"	19,	99	"	97	"

For the first four days it was an intermittent temperature with a wide daily range of fluctuation, specially marked by fall of temperature on four occasions to 96° or 97°. For seven days the temperature was remittent in type varying between 100°–102°, sometimes 103°. On the twelfth day it rose to the highest point—106°, and subsequently fluctuated between 104° and 96° or 97° until the day of his death. During the last six or seven days of the illness the temperature was very irregular, showing its maximum between 12 midnight and 12 midday, but was low at 7 or 8 A. M.

The typhoid state was present during most of the illness, but although the liver was defined as enlarged there was never any pain or tenderness, no jaundice, no tympany, or, in fact, a single symptom to draw attention to the liver save the increase in size, which was not extreme or greater than is frequently observed in remittent fevers. During the illness there was no pain or tenderness over the region of the stomach, and only one or two stools daily. It was, however, noticed that the general symptoms of illness would markedly increase during a certain portion of the day, and that during the remission of the temperature the condition of the patient would become conspicuously improved. There was one slight chill, and once an attack of epistaxis. The symptoms of the pulmonary conditions were latent.

The diagnosis in this case was subject to debate until the death of the patient, typhoid or typho-malarial fever, and hepatic abscess being canvassed, but the entire absence of any special local symptom connected with the liver caused the latter diagnosis to be laid aside until the duration of the case rendered the above named fevers unlikely.

In the diagnosis of hepatic abscess it must be borne in mind that the condition is often latent. The symptoms have been classified under the rational and the physical signs in connection with an analysis of the etiological probabilites. With these methods of study, hepatic abscess must usually be recognized by exclusion, since the symptoms are by no means pathognomonic, and the diagnosis must be manifest or obscure in proportion to the presence or absence of signs or symptoms which tend to locate the process of the disease below the diaphragm.

One of the most important symptoms in this connection is the thoracic character of the breathing and the deficient diaphragmatic movement. This is due to the presence of local or general peritonitis, especially the peri-hepatitis so often observed.

In thirteen cases recorded by Carrington,[1] general peritonitis was observed in four, while in six the local peritoneal process was found, and yet in the case I have presented the abdominal distention was not noticeable, although at times the abdominal muscles were hard with rigid recti. Abdominal pain and tenderness might be considered an important symptom, and appeared in twelve of Carrington's cases, but was absent in nine.

The temperature in multiple hepatic abscess is especially valuable as a means of diagnosis, and I have compared the observations made by Carrington and others with my own, and have included the temperature recorded in certain cases of hypertrophic cirrhosis.

The special features of the thermometrical record

[1] Guy's Hosp. Rep., vol. 26, 1883.

worthy of remark were that there were many days on which the temperature was *subnormal*, and one should justly consider such a record as of high diagnostic value. But cases of multiple pyæmic hepatic abscess without pyrexia have been recorded by Murchison[1] and by Guitéras;[2] the temperature in a case of hypertrophic cirrhosis reported by the latter was noted carefully from October 21 to November 3, and found to be below normal in the mornings of ten of these days, once as low as 91°, once 94°, once 95°, and several times 97°. In this case, however, it is true that the evening temperature was not very high, only on four days being over 100°, and several times showing a record below 98°. Dr. Guitéras, in commenting on the temperature thought it might be due to an intermittent absorption of effete products from the liver, or an intermittent arrest of the oxygenating processes going on in the liver, an arrest that must influence the general temperature, if we remember that in health the temperature of the liver reaches 106°.

The case of hypertrophic cirrhosis by Carrington shows that the temperature taken for twenty-four days gave $100\frac{6}{10}$° A. M., 103° or 104° P. M. on several occasions, and was for twenty days fluctuating between 99° and 101°, with an occasional fall to 98°.

Murchison and Frerichs mention that there may be a slight degree of fever in hypertrophic cirrhosis, but seem to allude to the rise in a way that suggests their belief that it may have followed some imprudence of diet or unusual excess in stimulants or succeeded a chill. Thierfelder (Ziemssen's *Ency.*, vol. 9) alludes to a rise of temperature as an exceptional feature under the same general circumstances.

Carrington, in reporting fifty cases of cirrhosis of the liver uncomplicated by lesions which would of themselves cause fever, has found a considerable number of cases with a febrile movement similar to that recorded, and has published examples of the same, and this fact in connection with hypertrophic cirrhosis is of especial interest, since Fouquier observes that it is the peculiarity of parenchymatous organs and particularly of the liver to occasion no fever even when they are the seat of intense disease. It is, however, a fact that the pyæmic state is attended by wide fluctuations of temperature and in abscess of the liver a subnormal temperature is often observed. (See also vol. ii., *Trans. Pathological Society of Philadelphia*, Eskridge.)

Nancrede, of Philadelphia, has alluded to the fact that a subnormal temperature is characteristic of abscess in the brain substance. I do not know that his observations have been confirmed by others, yet the statement is very interesting when one is considering the question of abscess in the parenchyma of organs. In abscess of the liver it would also appear according to Annesley, Haspel, Louis, and others, as quoted by Frerichs, that this intermittent type of temperature may resemble malarial quotidian, tertian, quartan, or a double type, but differs in the irregularity with which the attacks come on, and the inutility of quinine.

It is especially noteworthy in consulting the records of cases that sweating although present at times, is neither a constant nor prominent symptom of hepatic abscess, and that rigors are far more often absent than present; and the fact recalls Fouquier's observation relative to the temperature in hepatic disease already cited. But if the abscess ruptures spontaneously or is opened, sweating becomes the common rule. The pulse and respiration are usually quickened in accordance with the exacerbations of temperature, but except during this period the pulse is slower in my experience than in other pyæmic or typhoid fevers.

In multiple pyæmic abscess of the liver, the more or less complete typhoid state with dry brown tongue and sordes on the teeth is quite a constant but not invariable accompaniment. Wasting is usually a prominent symptom throughout.

It will be remembered that in the case which formed the basis of this paper the liver was recognized during life as enlarged. A similar increase in size was observed in all of Carrington's cases but the last; the maximum increase in size measured from the third rib to one inch below the margin of the ribs, and subsequently increased from half an inch to an inch. But in hypertrophic cirrhosis I have frequently found the area of deep dulness to extend from the fourth interspace to two inches below the margin of the thorax in the line of the nipple. I incline to think that the enlargement of the liver in abscess is only a relatively important sign, since in addition to the forms of cirrhosis with enlargement considerable increase in the size of the liver is often recognized in prolonged remittent fevers.

The sense of fluctuation is seldom recognizable in multiple pyæmic abscess which, as shown in the specimen, are small or lie too deep, but obviously this symptom would have a high diagnostic value. The remaining symptoms often presented in reports of cases of pyæmic hepatic abscess would seem to me to possess a minor importance. In Carrington's cases, for instance, jaundice was observed only in one-third the number of histories. Curiously, while it was a marked symptom in two cases, one with complete obstruction of the ducts, it was also present in a case without this condition. It was slight in two other cases; in each of which, however, the urine contained bile, and in two others the complexion was sallow and yellowish. Symptoms referable to the stomach and bowels, such as vomiting or diarrhœa, would seem obviously connected with lesions within the alimentary tract, such as dysentery, gastric or duodenal ulcer. I allude especially to this point, because in my case serious gastric lesions were present without the occurrence of vomiting or symptoms of gastric distress, and this, notwithstanding that the administration of food and stimulants was pushed to its furthest limits.

Finally the duration of the illness in pyæmic abscess varies widely. In the thirteen cases of Carrington, eighty days was the longest, and five days the shortest period of duration; but the condition of the related viscera must govern the prognosis so far as time is concerned, and this coincides with the views of Murchison and Frerichs; also when the

[1] Diseases of Liver, p. 175.
[2] Transactions Philadelphia Pathological Society, vol. 8.

abscess opens into the viscera or externally life is much prolonged.[1]

Last of all, the etiology of the disease should be a prominent factor in any bedside study, although I confess I believe the etiology of an hepatic abscess is more frequently studied at the post-mortem table. The classification of Murchison, which divides hepatic abscesses into two varieties, pyæmic and tropical, is most satisfactory. In the first class are placed all those cases which originate from external injuries or surgical operations, from ulceration of the stomach, intestinal canal, gall-bladder, bile-ducts, cervix uteri, or from any other source of purulent absorption, and in which the abscesses are small, round, and numerous. It is this variety of abscess which is almost, if not exclusively, met with in the temperate zone. In addition to the foregoing cases the portal vein should always be examined for evidence of phlebitis or thrombosis. The etiology of many cases can be explained on this basis, as can be seen in the accompanying specimen.

The second class embraces those which originate in tropical climates, in which suppuration cannot be ascribed to dysentery or to a pyæmic source, or to mechanical violence, and in which it is exceptional to find more than one large abscess—in a word, this species of abscess would seem to follow acute idiopathic inflammation of the hepatic tissue.

The distinction seems chiefly to be an etiological one, for while in typical examples of either group the symptoms and physical signs are somewhat different, there are other cases where they are identical, and the distinction founded on anatomical conditions, such as large size, small number (one to three) of tropical abscess, with tendency to burst externally into the pleura, lung, or intestinal canal, as contrasted with the opposite character of pyæmic abscess are not always observable.

The specimens from the case of ulcerative endocarditis, which I shall also present with the narrative of the symptoms, have suggested thoughts which seem related to what has gone before, chiefly because the pyæmic type of temperature is a marked clinical feature in this process.

James G., aged thirty-eight, Irish, was brought to the Philadelphia Hospital, February 1, 1886. He had a severe chill while in the ambulance, and the temperature on admission was 105° F. He stated that for six months he had been broken down in general health, that he had contracted malaria in Ohio last spring, and had suffered occasionally from chills and fever ever since July. For the last six weeks he had been confined to bed with occasional chills with fever. His appearance was that of a fairly nourished man of large frame but quite anæmic. The spleen was found to be enlarged, a soft double aortic murmur was audible up and down the sternum. The temperature record was:

Feb.	1,		A.M., 105°	2 P.M., 104°	7 P.M.
"	2,	99.3°	" 99	"	
"	3,	98	" 106	"	
"	4,	102	" 102.4	"	
"	5,	100	" 101.4	"	
"	6,	97	" 103	"	

Death at 11.45 P.M.

[1] See statistics on this point in Frerichs's Diseases of the Liver.

He rose from bed five days after admission to go to the water-closet, and fell dead while crossing the ward.

The post-mortem examination was made sixty-two hours after death. On opening the heart, the aortic valves were found to be the seat of the principal lesion. The intercoronary leaflet was perforated near its right border. The torn and ulcerated surfaces were very ragged, and large fungous warty vegetations were attached to the surfaces, forming a bridge connecting the intercoronary valve to the left anterior valve. These vegetations appeared as though they had been recently torn through, and that the giving way of this part of the valve had been the immediate antecedent of the sudden death. The right valve had its posterior portion ulcerated through, and along the margin of the valve the border was thickened and soft. The left coronary valve was uninjured except at one small point to which was attached a filament of the vegetation already mentioned. The affected surfaces had a reddish-gray color. There were a few patches of atheroma near the valves, and the lining membrane of the aorta was in some places covered with lymph. The aortic arch was unaffected. The heart weighed thirteen ounces. The muscle was of good color, but soft and flabby. The right ventricle contained a buff colored clot which extended into the left auricle and pulmonary artery. The tricuspid and pulmonary artery valves were healthy. The left ventricle was dilated. The anterior leaflet of the mitral valve was somewhat thickened at its border. The spleen was more than double its normal size. Its consistency was increased, and its capsule thickened. There were no embolic infarctions.

The liver was fatty and cirrhotic, slightly smaller than normal. The kidneys were both examples of fatty and parenchymatous nephritis. During life the case was supposed to be one of chronic valvular disease with malarial cachexia, and with breaking down of compensatory hypertrophy. This diagnosis was based upon the statements of the patient, viz., that he had been exposed to privation, with irregular chills and fevers, contracted in the West six months before. Moreover, there was enlargement of the spleen, and an anæmic, sallow appearance of the surface of the body. There was at no time albumen or casts in the urine, and no dropsy. The post-mortem examination has necessitated a revision of this diagnosis to that of acute endocarditis involving the aortic valve, exhibiting extensive ulcerative lesions.

The process known as acute endocarditis has been subdvided and separately described under the designation of ulcerative or malignant, as opposed to the simple inflammatory forms. Etiologically the infections nature of the disease is the prominent characteristic, and involves the study of certain microorganisms which have been found in connection with the endocardial lesions. In the present case the length of time which elapsed before the post-mortem could be made, rendered the search for these organisms difficult. Anatomically considered, the lesions of acute endocarditis have been described as vegetative, ulcerative, suppurative, and sclerotic. In the specimens presented this evening we have destruction of the valves by ulceration with vegetations.

Although no primary or secondary centres of embolic infection were found, the designation ulcerative endocarditis seems the only proper one. The disease in general is known to develop under many distinct associations. Rheumatism would seem, from recent writing, to be an infrequent but possible antecedent. Ulcerative endocarditis is sometimes secondary to pneumonia. In the case reported in this paper, the predisposing condition may have been the rheumatic diathesis, malaria, or the debilitated condition of the patient's general health, doubtless secondary to the alcoholic habit, which was markedly indicated by the post-mortem lesions.

The history of the patient is suggestive of the obscure character of the rational signs If we suppose a case in which, during an acute disease, evidences of valvular lesion develop, or if, during the progress of a case of old valvular disease, evidences of an acute process supervene, the salient physical sign suggesting the diagnosis of ulcerative endocarditis is, in the first place, the temperature. This differs somewhat under its different causative relations. In the cases I have seen the pyæmic character has been usually present, and profuse sweating has been common. This characteristic has been noticed by Dr. Henry Thompson,[1] as second only to that of ague, and usually far beyond the average mark of phthisis or pyæmia. In this disease, just as in pyæmic hepatic abscess, the intermittent type of pyrexia simulating a quotidian or tertian ague has been described by Wilks, Bristowe, Coupland, Lancereaux, and Leyden. Various cases are also related in which the diagnosis was yet more puzzling by the clear history of ague, and the attacks were so characteristic that a suspicion of malignant endocarditis was not at first entertained. It was only after the failure of quinine and a variation in the character of the paroxysms that a diagnosis was reached. The interpretation of the temperature chart in this disease may also be rendered difficult by the duration of the symptoms, which in one case of ulcerative endocarditis was prolonged to four months, and in this connection the statements of my patient as to the commencement of his ill-health may be recalled. The temperature in ulcerative endocarditis is naturally affected by the complications, such as croupous pneumonia,[2] and the typhoid type of temperature may at times suggest the diagnosis of typhoid fever, just as a similar chart in multiple hepatic abscess suggests the same thought; but the irregular temperature, possibly the sweatings, the early typhoid state, and the general want of conformity to the well-defined picture of typhoid fever, suggest the differentiation, and it might be added that rigors rarely occur in typhoid fever, but are common in endocarditis. The remittent or typhoid temperature with moderate febrile movement (*i. e.*, one or two degrees) is often observed in those cases in which the recent malignant endocarditis is engrafted on the subjects of chronic valve disease,[3] but even in these cases the morning temperature is often 98°, and the duration of this phase of temperature may be very prolonged. Dr. Green refers to a case which lasted six months, and to another in which during eighteen months there were attacks of irregular fever. Osler writes, "I have noticed the febrile symptoms subside for weeks, to recur again with increased severity, and there are cases which render it probable that the process may subside entirely, or the temperature may be sustained at 102° to 103° till the end of the case."[1]

It would, therefore, appear that the peculiarities of temperature in ulcerative endocarditis afford very valuable grounds for diagnostic deductions, the most extensive and destructive atheromatous changes can occur without elevation of temperature, but withal Dr. Sansom[2] has referred to a case of ulcerative endocarditis in which there was no elevation of temperature throughout. The study of the compensative hypertrophy seems to me of decided value from the diagnostic standpoint. In the case I have reported we have presented a temperature with the foregoing characteristics, with an aortic murmur, but without the signs of compensative hypertrophy which should accompany a chronic lesion. The enlargement of the spleen noticed in the case I have reported is frequently observed, especially if the alternations in temperature are extreme. Pain, palpitation, or subjective cardiac symptoms may be present, but the process is often latent.

In a case of valvular heart disease with the temperature described occurring without association with rheumatism, and with the history of an acute illness, the diagnosis of ulcerative endocarditis is strongly suggested. Even in cases of chronic valve lesions the outbreak of fever with rapid disturbance of the balance of a previously perfect compensation without rheumatic history, presents the same suggestive diagnostic features. The probabilities in favor of the diagnosis of ulcerative endocarditis would be strengthened if evidences of embolism in the various viscera, especially in the pulmonary circuit, occur, or if cerebral symptoms are added to the picture.

CONGENITAL TUMOR OF THE RECTUM.

By W. H. HAYNES, M.D.,
of New York.

In vol. 26, page 584, of the *Medical Record*, there is reported the following case of *congenital hemorrhoid*, perhaps due to an inherited predisposition or maternal impression, and of an external variety.

"A female child was born of healthy parentage. The mother, a primipara, had always been the picture of health excepting chronic constipation, and its natural result hemorrhoids, which have been many years a source of torment to her, and was naturally extremely aggravated by pregnancy. The child, otherwise well formed, presented at the verge of the anus on the right side a fold of skin projecting three or four millimetres from the normal level of the epidermis, and five millimetres long by three broad. This is covered with healthy normal integument of natural color and sensibility. It is then an *imitation* of a pile just where the mother's most annoying tumor was located. The little tumor seems to be merely an excess of skin at that point, and is in color and texture so like healthy skin

[1] Gulstonian Lectures, 1885.
[2] Lancet, vol. i. 1884.

as to show that it cannot be the result of inflammation. The mother was very anxious to know if her baby 'had piles,' and said she had been praying for months that her child might be spared an affliction which had caused its mother so much suffering."

I now take the opportunity of reporting a case of what may be termed an example of the internal variety of congenital hemorrhoids.

Mrs. H. was delivered of her second child, a female, which, on the day of its birth, was noticed to have hanging from the anus, at each stool, a globular tumor about the size of a small cherry-stone. It was dark red in color, and suspended by a short pedicle from just above the muco-cutaneous border of the anus within the rectum on its right side. No hemorrhage attended its appearance, and it was semi-solid to the touch. It was seized with a pair of forceps, which caused slight bleeding. A silk ligature was tied around the pedicle at its base. On the morning of the third day after this, the tumor fell off during a stool, and was thrown out with the excrement contained in the diaper. When I saw the child a few days later there was nothing unusual to be noticed about the anus, except a little point of ulceration just within its border, at the seat of the former location of the tumor. There was no reason to suspect any predisposing influence other than that the mother was afflicted with internal hemorrhoids.

I have nowhere been able to find a case recorded similar to either of the above.

Objections may be raised to the term *congenital hemorrhoids*, yet it certainly succinctly describes both the conditions found, better than any other that could be mentioned, although it may seem inconsistent to name a congenital growth after a disease, though they resemble each other in every respect except as to cause. It may be thought that the last was a case of polypus of the rectum; as to that, I would mention that its location and appearance were certainly not those of the soft gelatinous polypi met with in children, nor of the hard fibrous variety of tumor found in adult life, but it resembled more than anything else what is erroneously termed "hemorrhoids or piles," and which is found in both young and old.[1]

In neither case were the contents of the tumors noted. Both patients were females.

As to any predisposing or maternal influence, I would rather not speculate, as the observations are too few, and we are yet in the dark regarding the workings of nature in this direction.

HOSPITAL NOTES.

NOTES FROM THE PARIS HOSPITALS.

(Specially reported for THE MEDICAL NEWS.)

LOBULAR PNEUMONIA; SEPTICÆMIA; DEATH.

M. HARDY recently gave an interesting clinical lecture, at the Charité Hospital, on a case of lobular pneumonia followed by septicæmia, and finally death. The patient was sixty-four years of age, and he had never previously been seriously ill. During eight days before he entered the hospital he had been ailing—a pain on the right side of the chest and a cough. Nevertheless he continued to work up to ten days before his admission. When he was admitted he coughed a great deal; his sputum was viscous but not abundant. Sibilant and subcrepitant rhonchi were heard on both sides; the temperature varied from 102.2° to 104° F., and the pulse beats were from 100 to 110 per minute. The symptoms were somewhat contradictory; they indicated tracheo-bronchitis, and the stitch in the side was symptomatic of another condition. Fever increased, also the pulsations, from 110 per minute to 116; the patient was excessively prostrated, the eyes were bright, and the stitch in the side intensely painful. The sputa did not present the coloration peculiar to pneumonia, they were of a greenish-yellow color, but their consistency was that of the sputa of pneumonia. On auscultation subcrepitant rhonchi were heard in the right armpit; in the subscapular region bronchophony was detected. On percussion there was decided dulness. Respiratory vibrations were heard below the souffle and the sibilant rhonchi; they were also present on the left side. Bronchitis was diagnosticated, complicated with lobular pneumonia of the right side. The patient was dry-cupped and a Todd's potion administered. The stitch in the side disappeared, but on the fifth day after the patient was admitted (March 13) the temperature was 104° Fahr., and the pulse beat 120 to the minute, all the other local symptoms remained—dulness, souffle. M. Hardy ordered a full dose of tartar emetic every two hours, and directions were given to the nurse to discontinue the dose after three attacks of vomiting or three motions, or after three times vomiting and one motion. The last condition was realized and the emetic was no longer administered.

The patient considerably improved. His temperature fell to 102.4°, and the pulse to 110; local symptoms were also favorably modified, and the crepitant râles were changed to mucous râles. The improvement was maintained during two days; on the third fever returned, the temperature was 100.5° to 104°; on the fourth it rose to 105.9° in the evening; the patient was physically distressed and slightly delirious. He was carefully examined but no fresh symptoms were detected, no indications of a recurring pneumonia; the sputa were not viscous as at the onset of the malady, and only a slight dulness remained.

On the sixth day after the temporary improvement in the patient's condition, the prognosis was most serious; the morning temperature rose to 104.1°, the pulse 174 to the minute. Neither auscultation nor percussion revealed any indications of a return of pneumonia. The patient died the same night, twelve days after his entrance and twenty days after the actual onset of his illness.

The necropsy revealed the following condition: extreme congestion of both lungs, several patches of hepatization in the central region of the right lung. The spleen was considerably enlarged and diffluent, as in septicæmia; the kidneys enlarged and congested, resembling those in infectious nephritis; the liver likewise was much enlarged, presenting small detached patches of fatty degeneration; the gall-bladder contained three large green calculi. During lifetime the patient's skin was slightly jaundiced. The mitral valve of the heart was slightly altered, but that was evidently of long standing.

[1] Allingham, fourth Amer. ed., p. 52.

Thus the necropsy revealed all the characteristics of septicæmia. Death resulted from a general condition impossible to account for, and perfectly independent of the pulmonary affection. The patient was a bootmaker, a calling which does not throw any light on the etiology of his infectious condition, resulting in death.

Fatal Pneumonia attacking Husband and Wife; Pneumococci detected.—Alphonse and Marie P. were both servants at the Pitre Hospital; they had been there during four years; the husband had never been ill; Marie had been ill with quartan intermittent fever, with lung complications. Their bedroom was small but airy. Marie was suddenly seized with shivering fits and a stitch in the left side; she was very feverish; there were sibilant and loud râles on both sides of the chest; at the base of both lungs subcrepitant râles; in the armpits small subcrepitant rales; her voice had been excessively hoarse for three days. Eight days before her illness she complained of feeling ill, of having pains all over her; she had a bad cold in the head, and was in the sixth month of pregnancy. The diagnosis was influenza, with pulmonary congestion on the right side. Pregnancy explained the dyspnœa, which greatly distressed the patient. Todd's potion was prescribed and dry cupping.

The patient passed a good night. The next morning she was much better, but her husband, Alphonse, was seized with a shivering fit which lasted two hours; he had a burning, hot skin, temperature was 104.7°, and he complained of a constant pain in the left side; no cough, no expectoration; it was impossible to diagnosticate the acute affection from which the patient was suffering. The next day symptoms of pneumonia declared themselves, these became more and more serious, and the patient died on the fourth day of his illness.

Marie, the wife, was delivered of a seven months' child two days after she was taken ill. The child lived, and the mother continued to suffer from dyspnœa, and exhibited symptoms of bronchitis; she died four days after her confinement, the fifth day of her illness.

The treatment consisted of full doses of alcohol, dry cupping, and bromhydrate of quinine. A necropsy was not allowed by the relatives. The rapid and serious character of the pneumonia remains unexplained. The sputa contained numbers of Friedländer's lanceolate encysted microbes.

MEDICAL PROGRESS.

A HYGIENIC SCHOOL DESK.—DR. PRIESTLEY SMITH has devised a hygienic school desk which he describes in the *Ophthalmic Review* for June, 1886. The requisites for such a desk he formulates as follows:

1. The seat must be of such height as will allow the scholar's feet to rest flat upon the floor or footboard, and broad enough to support the greater part of the thigh.

2. The seat must have a back placed at such height as to fit the hollow of the back below the shoulder blades, and support the body in a vertical position.

3. The near edge of the desk must be just so high above the seat that when the scholar sits square and upright with elbows to the sides, the hand and forearm may rest upon the desk without pushing up the shoulder.

4. As used in writing, the desk must have a slope of 10° to 15° (about 1 in 5); as used in reading, it must support the book at an angle of about 45°, and at a distance of at least twelve inches from the eyes—sixteen inches is better (30–40 centimetres).

5. As used in writing, the edge of the desk must overhang the edge of the seat by an inch or two, in order that the scholar shall not need to stoop forward, and that the support to the back may be maintained.

6. Either the desk or the seat, or some part thereof, must be movable at pleasure, so that although the desk usually overhangs the seat the scholar may be able at any time to stand upright in his place.

7. The desks and seats must be of various sizes, in order that the foregoing conditions may hold good for scholars of various ages.

ON THE PLACE OF ORIGIN OF URIC ACID IN THE ANIMAL BODY.—In a paper read before the Royal Society, June 10, 1886, by ALFRED BARING GARROD, M.D., F.R.S., and reported in the *Chemical News*, the endeavor of the author has been to show the place of origin of uric acid in the animal body, and to ascertain which of the two hypotheses on the subject is correct, viz., whether uric acid is first present in the blood, and then secreted from the blood by the kidneys, or whether it is formed by the kidneys themselves. To enable him to prosecute satisfactorily many of his observations, the author has devised a new method for discovering the presence of uric acid in very minute quantities of blood.

The results of his investigations are embodied in the form of the nine following propositions:

Prop. I. Uric acid is secreted by the kidneys as ammonium urate; and in the case of birds and reptiles, whose urine is semi-solid, it is found in a definite physical form, more in the vitreous condition than in the truly crystalline shape.

Prop. II. Uric acid, when present in the blood, is found under the form of sodium urate; and, when deposited from the blood during life in any tissue, it is also as sodium urate in its characteristic crystalline form.

Prop. III. The quantity of uric acid daily secreted by different animals in relation to their body weights varies extremely. In some, as the carnivorous mammalia, the ratio may be less than 1 to 1,000,000, whereas in others, as birds, it may be as 1 to 85. In man it may be regarded as about 1 to 120,000.

Prop. IV. The quantity of uric acid contained in the blood of different animals has little relation to that secreted by the kidneys. In birds, secreting daily so large a quantity, the blood is often found to be as free from uric acid as it is in animals whose daily elimination of uric acid is excessively small.

Prop. V. When uric acid is absorbed from the alimentary canal, the blood becomes strongly impregnated, and, in fact, often almost saturated with it, so that its presence is readily discovered by any ordinary test.

Prop. VI. One cause of the appearance of an unusual quantity of uric acid in the blood of birds in health is the presence of uric acid in the water they drink, and occasionally in their solid food.

Prop. VII. When uric acid is taken into the stomach of man or other animals, the secretion of this principle from the kidneys is not increased, although at the time the blood may be rich in it.

Prop. VIII. Uric acid is found in varying quantities in the blood obtained from different veins in the same animal. It is found in larger quantity in that from the efferent renal veins than in that from the portal afferent, or from the jugular veins; and the same test which freely exhibits uric acid in the blood from the former often fails to show it at all in that from the latter two.

Prop. IX. The quantity of uric acid secreted daily by the kidneys of a bird is in close relation to the quantity of nitrogenized food taken during the time.

Having brought forward proofs to confirm these propositions severally, the author draws the following conclusions, viz., that every argument is in favor of the hypothesis that uric acid is formed by the kidney cells, in the form of ammonium urate, and that the traces of sodium urate found in the blood are the result of a necessary absorption, slight in amount, of the ammonium urate from the kidneys into the blood, and its subsequent conversion in that fluid into sodium urate.

Resection of the Rib for Gangrene of the Lung and Empyema.—Dr. K. Snellen, of Zeist, in Holland, having a case of pneumonia, which was followed by gangrene of the lung and empyema, aspirated, deferring opening up the cavity of the pleura for a few days. A fluctuating tumor being detected at the spot where the aspirator had been introduced, resection of the sixth rib, by the subperiosteal method, was performed, four centimetres being excised. When the pleural cavity was opened, an immense stream of extremely offensive fluid came away. The cavity was washed out, through a male silver catheter, with a three per cent. solution of boracic acid, and afterward with a one per cent. solution of chloride of zinc, the wound being covered with Lister's dressing. For the next two days the patient's condition was very much improved, but on the third day after the operation the temperature rose to 104.2° Fahr., and erysipelas of the face set in, which extended over the head and neck, the patient succumbing on the eighth day after the operation. It seems uncertain whether the gangrene was the direct cause of this erysipelas. The writer is disposed to think that in these cases it is better not to resect very early, but to aspirate first, so as to relieve pressure on the lung, and then, after waiting a short time for the patient's condition to improve, to evacuate and wash out the cavity. German literature on this subject is scanty. Schneider, of Königsberg, had a successful case of resection of the rib for gangrene, but the latter was of traumatic origin, being due to a gunshot wound, and therefore was less likely to be associated with so unhealthy a constitutional state as the present case, which was due to pneumonia. Dr. Snellen also suggests the practicability of repeated aspirations.—*British Medical Journal*, July 10, 1886.

Iodol in Ocular Therapeutics.—From considerable clinical and experimental experience A. Trousseau concludes that iodol is readily tolerated by the eye; that it may sometimes advantageously replace iodoform; that it ameliorates and sometimes cures ulcerative blepharitis, chronic conjunctivitis, and certain forms of vascular keratitis. It has been shown to be efficacious in phlyctenular keratitis and torpid ulcers of the cornea. In solution it favorably modifies granulations.

Trousseau, in this connection, recommends the following formulæ:

1.	Vaseline	5 parts.
	Iodol	1 part.
2.	Iodol	3 parts.
	Alcohol	35 "
	Glycerine	62 "

The pain resulting from the application of the solution is comparable to that caused by the ophthalmological use of nitrate of silver or sulphate of copper, and is chiefly due to the alcohol.—*L'Union Médicale*, May 22, 1886.

A Study of the Thyroid.—In an experimental research on the blood-forming organs and blood-formation in the *Journal of Anatomy and Physiology*, for July, 1886, Dr. John Lockhart Gibson summarizes as follows, the results of his experiments on the thryoid body:

1. That the thyroid has, properly speaking, no blood-forming function.

2. That any blood-forming action it may in some animals seem to have is due only to the presence of lymph-follicle-tissue in the thyroids of such animals.

3. That its function is in no way compensatory to that of the spleen.

4. That in dogs the total removal of the thyroid is always followed by death, after a definite train of nervous symptoms.

5. That in dogs the presence of unusually well developed aortic thyroid glands may prevent the onset of the symptoms.

6. That the removal of the whole thyroid from the human subject is unjustifiable, such removal being always, after a varying interval, followed by the development of the very serious definite condition called "cachexia strumipriva."

7. That in all excisions of the thyroid from the human subject at least a small piece should be left, a small piece appearing to be sufficient for the carrying on of the essential function of the gland.

8. That the function of the thyroid has special relation to the central nervous system, though what the true nature of such relation may be has yet to be definitely determined.

9. That myxœdema, cachexia strumipriva, and cretinism are probably one and the same disease, and are due to virtual or actual absence of the thyroid.

Olfaction.—Aronsohn (*Du Bois's Archiv*, 1886, Heft 394) has made a long series of experiments upon this subject in man. He found:

1. That the olfactory nerve was completely blunted for a time through the uninterrupted action of an adequate irritation in the course of a few minutes.

2. Completely exhausted olfactory nerves need at least a minute for complete recovery.

3. Different kinds of odors affect different territories of the olfactory region; one territory is excited to a maximum degree, a second territory in a lower degree, and a third territory not at all.—*Journal of Nervous and Mental Disease*, June, 1886.

Applications of Glycerine in the Treatment of Simple Ulcer.—Demarquay speaks highly of

the following mixture as applied to simple indolent ulcer:

Glycerole of starch	5 parts.
Sulphate of alumina and zinc . .	1 part.

Where the ulcer is painful he uses a dressing thus composed:

Sydenham's laudanum . .	4 to 5 parts.
Glycerine.	100 "

Such dressings are found to be of advantage whether the ulcer be scorbutic, scrofulous, or syphilitic.—*L'Union Médicale*, No. 55, 1886.

On Vaginal Extirpation of the Uterus.—Dr. Brennecke, in the *Zeitschrift für Geburtshülfe und Gynäkologie*, vol. xii. part i., states that he has removed the entire uterus through the vagina for cancer eighteen times, without a single death. His first principle is to make the parts as accessible to the surgeon's hand as possible throughout the operation. For this purpose he has devised a special uterine clamp-forceps, which takes up little room, and grasps the tender and friable uterine tissue firmly, yet safely. He takes special precautions against hemorrhage. He carefully cuts through the upper reflexion of the vagina, in front and behind, with a short-bladed knife, shaped like Küchenmeister's, and separates the cervix from the loose surrounding cellular tissue. Then he isolates the denser tissue on the sides of the cervix, bearing the uterine artery and its branches. The operator then grasps the uterine appendages. Each appendage is ligatured by means of a strong S-shaped needle, resembling that devised by Olthauser, which introduces the thread with comparative facility. The uterus is then strongly retroflexed, and pressed closely against the posterior wall of the vagina: by this manipulation the vesico-uterine fold of peritoneum is most readily separated without injury to the bladder. An elastic ligature is then applied to the broad ligaments, and they are cut through. Dr. Brennecke neither drains Douglas's pouch, nor applies any suture to its divided serous surfaces. An iodoform-glycerine plug sufficiently protects the escaping discharge from septic changes. After six or seven days the plug is removed, and the vagina is simply irrigated. Dr. Brennecke prefers total extirpation to amputation of the cervix, and even advocates vaginal extirpation for other incurable uterine diseases, in preference to abdominal section or oöphorectomy. His monograph is of great importance, and his method of operating can only be thoroughly understood by a perusal of the same. It need hardly be added that statistics of after-histories are even more important in this case than after ovariotomy and myomotomy. The most dexterous operator might, physically speaking, cut away a cancerous growth, the limits of which are tangible, if not visible, on a breast, removing an infinitely small area of healthy tissue around the growth. We know that he does not do so, but cuts very freely, and is able to use the knife boldly, thanks to the anatomical relations of the breast. In the case of the uterus, the greatest dexterity may fail to remove all the cancerous tissue, especially if it have spread to the connective tissue round the cervix, and cutting freely is out of the question; nor can the finger always detect the extension of the disease. This must never be forgotten when any operation on a cancerous uterus is contemplated.—*British Medical Journal*, July 10, 1886.

Drunkard's Epilepsy.—In view of Magnin's assertion that in France the frequent cases of epilepsy occurring in drunkards are due, not to alcohol but to absinthe, Moeli has reviewed the German statistics of the subject which may be thus summarized:

In Germany 36 to 40 per cent. of the subjects of delirium tremens a' also victims of epileptic attacks. An attempt to determine whether the occurrence of such attacks was correlated with the abuse of any special kind of distilled liquor was unsuccessful, but it was found that in twenty-six almost exclusively beer and wine drunkards only one was epileptic.—*Centralblatt für klin. Med.*, No. 11, 1886.

Gunshot Wound of Heart; Patient Survived Forty-two Hours after Injury.—Surgeon G. F. Nicholson, M.D., of Peshawar, India, relates the following case: Poor Dil, a resident of Bahadur Killi, a short distance from Peshawar, was shot through the chest about 9 o'clock on the night of the 9th of March, 1886; he was brought to the Egerton Hospital at 6 o'clock the following morning, and was then almost pulseless, had extreme difficulty in breathing, and occasionally coughed up blood. Shortly after admission to hospital he rallied slightly; but remained very low till death took place at 3 o'clock P.M. on the 11th of March.

There was a circular wound on the posterior fold of the left axilla, half an inch in diameter, and evidently leading to the lung, blood and air escaping through it. The bullet, a round one, was felt on the right side of the chest immediately underneath the skin, and was extracted through a linear incision; through this wound too blood and air escaped. On post-mortem examination the course of the bullet wound was found to be as follows: Through the seventh rib on the left side, some pieces of which were found in the left lung, then through the left lung, left and right auricles of heart, through the right lung, and finally through the fifth intercostal space on the right side. Blood was found in large quantities in both pleural cavities, and about one ounce of blood stained serum in the pericardium. There were two long rounded blood clots extending from the wounds in the right and left auricles into their corresponding ventricles; the lower portions of these clots were almost quite white.

That a man should live over forty hours after such a grave injury is very remarkable and important in a medico-legal point of view. Bryant mentions a case recorded in Circular No. 3 of the War Department of Washington, in which the right auricle was wounded, the patient surviving fifty hours.—*Indian Medical Gazette*, May, 1886.

How to Cool a Cellar.—A great mistake is sometimes made in ventilating cellars and milk houses. The object of ventilation is to keep the cellars cool and dry, but this object often fails of being accomplished by a common mistake, and instead the cellar is made both warm and damp. A cool place should never be ventilated, unless the air admitted is cooler than the air

within, or is at least as cool as that, or a very little warmer. The warmer the air, the more moisture it holds in suspension. Necessarily, the cooler the air, the more this moisture is condensed and precipitated. When a cool cellar is aired on a warm day, the entering air being in motion appears cool, but as it fills the cellar the cooler air with which it becomes mixed chills it, the moisture is condensed, and dew is deposited on the cold walls, and may often be seen running down them in streams. Then the cellar is damp, and soon becomes mouldy. To avoid this, the windows should only be opened at night, and late—the last thing before retiring. There is no need to fear that the night air is unhealthful—it is as pure as the air of midday, and is really drier. The cool air enters the apartment during the night, and circulates through it. The windows should be closed before sunrise in the morning, and kept closed and shaded through the day. If the air of the cellar is damp, it may be thoroughly dried by placing in it a peck of fresh lime in an open box. A peck of lime will absorb about seven pounds or more than three quarts of water, and in this way a cellar or milk room may soon be dried, even in the hottest weather.—*Scientific American.*

THE FATE OF EXTRAVASATED BLOOD.—DR. HUNTER has presented to the Scientific Grants Committee of the British Medical Association an experimental research thus entitled, of which the following *résumé* is given in *The British Medical Journal* of July 17, 1886.

The object of research was primarily to determine the share taken by the liver, the spleen, and the bone marrow, in the disposal of extravasated blood. The method of research was the transfusion of large quantities of blood into the peritoneal cavity, the blood being, in all cases, derived from an animal of the same species. The animals used were the rabbit and dog.

I. *Local Fate.*—1. The part taken by cells in the local changes going on around extravasated blood is of the greatest importance; the cells being of two kinds—those of leucocyte, and those of connective tissue origin.

2. The formation of blood-pigment from the red blood-corpuscles is mainly a "cellular" process, being effected through the agency of cells, either by inclosure of the corpuscles bodily within them, or by disintegration of the red corpuscles and then inclosure of their fragments.

3. In the process of so-called "organization" of blood-clot, both varieties of cells play an important part; but while both leucocytes and connective tissue cells are concerned in the disintegration of the red corpuscles, the former, in addition, effecting the removal of the *débris* from the seat of extravasation, the connective tissue cells alone are concerned in the process of formation of fibrous tissue by which ultimately the clot becomes replaced.

II. *Absorption.*—4. The absorption of extravasated blood applies not only to the serum of the blood, but also to the great majority of the red corpuscles which remain unentangled amidst coagula or the surrounding tissues.

5. This absorption is extremely rapid from the subcutaneous tissues, and especially from the larger serous cavities.

6. In the case of the peritoneal cavity, the absorption of the serum and red blood-corpuscles is effected almost entirely through the lymphatics of the diaphragm.

7. Under such circumstances the increase in the number of corpuscles within the circulation is observable one hour after injection, and steadily rises till it reaches a maximum about the second or third day, the time varying according to the quantity injected.

8. Extravasation *per se* does not affect the vitality of the red blood-corpuscles; if absorbed back into the circulation within a day or two, they continue to live as before.

9. Their longest duration of life under such circumstances (in the rabbit) varies from two to four weeks, this duration applying naturally to only a few of them.

10. The probable life-duration of the red blood-corpuscle in man is about three weeks.

III. *Ultimate Fate of the Absorbed Blood-corpuscles.*—11. The three great seats of blood destruction within the body, under pathological as under physiological conditions, are the liver, the spleen, and the bone marrow.

12. The nature of the process of destruction in the liver differs essentially from that in the spleen and bone marrow.

13. In the latter, the process of blood destruction is mainly a cellular one, comparable in all respects with, although much more rapid and complete than, the similar processes taking place locally at the seat of extravasation; in the former, the destruction is much more rapid than in the spleen and bone marrow.

14. After increased destruction of blood-corpuscles within the body, the local evidences obtainable are—in the case of the liver, increased richness of its substance in iron and the presence of granules containing free iron within the liver-cells; in the case of the spleen and bone marrow, increase in the amount of pigment containing free iron found within these organs.

15. In health, a definite relation is maintained between the amount of blood destruction which takes place in the liver on the one hand, and in the spleen and bone marrow on the other.

16. Any disturbance of this relation on the part of the liver is of much greater consequence than on the part of the spleen or bone marrow.

17. The former is, in all probability, the pathological change which lies at the root of progressive pernicious anæmia; as the latter is the probable cause of the anæmia of leucocythæmia.

18. The rapidity with which blood-corpuscles introduced into the circulation become destroyed is very great, a number equivalent to about four or five per cent. of the animal's own blood being destroyed daily.

19. The small quantity of blood transfusible into the organism in the case of man is therefore entirely removed from the body in a few days at most, probably not longer than three or four.

20. Transfusion of blood in the human subject, in cases of pernicious anæmia, with the object of increasing the number of corpuscles, is devoid of all physiological basis, and is simply adding fuel to the flame, since the fault in this disease is not one of defective formation of blood-corpuscles, but one of excessive destruction of those already present.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, JULY 31, 1886.

THE SPONTANEOUS RUPTURE OF TENDONS.

IN connection with the subject of the treatment of divided tendons, to which we referred last week, attention may be usefully directed to the consideration of the causation of spontaneous ruptures of tendons. These, according to the classification of Volkmann, are distinguished from traumatic ruptures by the fact that they are caused by muscular action so slight as to be devoid of danger to healthy tendons. They correspond to the ruptures of muscles or bones which are caused by coughing, sneezing, or vomiting, and which are likely to occur after, or during severe constitutional diseases, such as typhoid fever, which lead to fatty or amyloid degeneration.

In otherwise healthy individuals a tendon may likewise rupture after it has been weakened at some spot by disease. In the experience of HAGER, as related in the *Berliner klin. Wochenschrift*, for May 31, 1886, teno-vaginitis, or what, in this country, is usually called tenosynovitis, is a frequent cause of such a weakening of a tendon. It would be interesting to collect some information from other sources in regard to this point, but the cases cited by Hager seem to support his opinion that chronic inflammation of the sheath of a tendon may lead to softening of the tendon itself, and make it liable to break under a comparatively slight strain. On the other hand, Hager's conception of the mechanism of the rupture of the tendon in his own and in like cases is open to criticism. He states that this occurred in his patient while he was pressing pieces of gutta-percha against a polishing wheel, the thumb being used to make the pressure, and being in a semiflexed position. This Hager understands to involve a relaxed condition of the extensor muscles and tendons. Herein, we think, he makes a very natural mistake. In most actions of the extremities, both the flexor and the extensor muscles are in a condition of almost uninterrupted activity. By coördination the exact effect intended is produced, and neither set of muscles overbalances the other. But there are occasions when, owing to some error in the operation of coördination, one set of muscles, or one muscle, or even only a part of a muscle, may suddenly contract in such a way as to disturb the previously existing harmony, and to cause quite unexpected and unintended movements, or even lead to rupture—a subject which has been admirably discussed by MAYDL in the *Deutsche Zeitschrift. f. Chir.*, Bd. xvii. and Bd. xviii., 1882 and 1883.

Hager attempts to explain the production of spontaneous rupture of tendons by stating that contraction of a flexor muscle may stretch the tendon of an extensor so much that it will give way, while the extensor muscle is still in a state of relaxation. Herein he states a paradox. A tendon cannot be put on the stretch without stretching the muscle beyond its limit of relaxation, and a muscle so stretched will resist and contract. This may be what actually happens in such cases, and would resolve the accident to a simple rupture caused by violent muscular action, differing in no essential from a rupture of the ligament of the patella by violent contraction of the rectus femoris. In fact, it seems as if the cramp which Hager describes as coinciding with the discovery of the loss of the power of extension in his case, might be attributed to a spasmodic contraction of the extensor muscle, causing a sudden increase in the tension of its tendon, and its rupture at a weak point. In this connection, we would suggest that the chronic tenovaginitis in Hager's case may have led to the formation of adhesions between the tendon and its sheath, with softening of the tendon below this point; and that an unusual contraction of the flexors, instead of breaking up the adhesions, resulted in breaking the tendon. Such a condition as this would make Hager's explanation reasonable.

The character of the union effected by operations by anastomosis or grafting, and the share in the result to be attributed to the union of the ends of a divided tendon with the cicatrix in the skin, are not yet clearly understood. It appears, from the observations so far recorded, that the tendons do unite. In a few cases it is stated that the cicatrix moved with every motion of the tendon, and it would not be surprising if this was always the case. But this does not militate against the opinion that the tendons are united; for it would be hard to understand how they could move without carrying

the cicatrix with them. If opportunity should arise to dissect a specimen in which this operation had been successfully performed, this question would be easier of solution. At present, the evidence seems to be in favor of the view which we have expressed.

OVULATION AND MENSTRUATION.

THE dependence of menstruation upon the ovaries is admittted by most physiologists, though different opinions are held as to the nature of this relation. The view that has hitherto been commonly received, and is still held by many, is that ovulation is periodical, the growth of an ovisac and its rupture corresponding with each menstruation. As the ovisac grows it presses upon ovarian nerves, and by reflex irritation causes congestion of the internal generative organs, especially of the uterus; the uterine hyperæmia results in hemorrhage from its mucous surface. Here the question arises as to whether this hemorrhage is facilitated by desquamation of the superficial epithelium, the result of a fatty degeneration, complete casting-off of the mucous membrane being rejected. According to some, this superficial desquamation does not occur until the close of menstruation, and therefore has nothing to do with the hemorrhage. Again, excellent authorities state that they have failed to find the proof of elimination of the superficial portion of the mucous membrane in menstruation. De Sinéty, in examining the discharge during the monthly flow, could not discover the least fragment of mucous membrane or of epithelium; so, too, in women dying while menstruating, he found the uterine mucous membrane entire in all its extent. Winckel says "Since Ruge and Moricke have found that during menstruation the ciliated epithelium of the uterine mucous membrane remains intact, an observation which we have repeatedly confirmed, the earlier view that during menstruation a fatty degeneration of the superficial layers was a cause of menstruation is incorrect."

Admitting these statements, the necessary conclusion is that the hemorrhage in menstruation occurs without destruction of any part of the uterine mucous membrane, and that the blood escapes from the superficial vessels, not by their rupture, but by diapedesis and through an intact mucous membrane.

The periodicity of menstruation can be most readily explained by attributing it to the ripening of an ovisac, for this, like other processes of growth, would naturally be supposed to require a certain time. Again, this interpretation of the connection between ovulation and menstruation corresponds with what we know of ovulation and "rut" or "heat" in animals, which is the analogue of menstruation. Nature's legislation is general rather than special, and it is not probable she would make one law relating to reproduction for animals in general, and then a special law for human beings.

But without pressing this point, let us see the proofs that are adduced to show that ovulation is not periodical. The results of Leopold's investigations are thus given by FOEKTISTOW in a recent number of the *Archiv für Gynäkologie*. Fully developed follicles, those already ruptured, and fresh corpora lutea may be found at any time during the intermenstrual period. These may not be present during menstruation. Hence, ovulation occurs without menstruation, and menstruation may occur without simultaneous rupture of the follicles. Ovulation, therefore, is independent of menstruation, and is not periodical. Nevertheless, while Leopold denies the dependence of menstruation upon periodical ovulation, he does make it depend upon the ovaries, and he regards its periodicity as placing it in the category of rhythmical manifestations—*e. g.*, the pulse, respiration, or ejaculation of semen.

The uterine hyperæmia results as a reflex from the ovaries caused, not by the ripening of an ovisac, but by the continued growth of several. Foektistow, in answer to the question, why does not menstruation occur more frequently, gives these reasons: Comparatively slight ovarian irritation is not sufficient to cause a reflex so soon. The essential, too, of the menstrual process is that anæmia follows hyperæmia, and irritability ceases. Equilibrium is thus restored, and to cause another reflex another sum of irritations is necessary, and these cannot occur at once. The changes in the uterine epithelium which began with the hyperæmia, pass away with the following anæmia, and the epithelium returns to its normal condition, a process which occupies more than one-half of the intermenstrual period.

Another theory of menstruation which is founded upon ovulation, is that of Lowenthal. According to him, the ovule reaches the uterus before impregnation; if it be impregnated, menstruation does not occur, but if it is not impregnated, it excites a uterine congestion which ends in hemorrhage. Winckel observes that the Achilles' heel of this bold hypothesis is that the death of the ovule can cause active congestion of the uterus. Further, this hypothesis is a revival of an old one—that is, menstruation results from the failure of impregnation, and is entitled to no more credence in its new than it was in its old form.

It may be, as stated by de Sinéty, that any positive theory of menstruation is, with our present knowledge, premature; nevertheless, it must be admitted that this function is connected with the ovaries, for if these organs are congenitally absent, or if they are undeveloped, menstruation does not occur. So, too, after double ovariotomy menstruation ceases. The exception to this rule cannot be

admitted until a careful post-mortem examination has proved that no fragment of ovarian tissue has been left behind in the lower portion of the pedicle, as has happened in some cases. Women have borne children after both ovaries were believed to have been removed. Olshausen performed, as he thought, ovariotomy; but the result being fatal, he found at the autopsy that neither ovary had been removed. Further, even if both ovaries have been completely removed, possibly there may remain a supernumerary ovary, a condition that Beigel's and Winckel's examinations prove to be far less rare than has been thought. Beigel found in 500 sections supernumerary ovaries 23 times; and Winckel has concluded, from his own examinations, that supernumerary ovaries are present in 3.6 per cent. Until in those cases of alleged normal menstruation, as stated by Foektistow, post-mortem examinations prove the entire absence of all ovarian tissue, the doctrine that menstruation depends upon ovarian action, will remain. So, too, it is in the highest degree probable that there is an intimate connection between ovulation and menstruation. At the same time it must be admitted that the two may be distinct, the one occurring without the other, though they are usually associated. Thus there may be occasional menstruations without ovulation, or the latter may occur without the former. Ovulation may begin before the first monthly flow and impregnation take place; during lactation it may occur without menstruation, and it may happen, too, after the menopause.

A FRENCH OPINION OF NITROUS OXIDE.

It is said that ideas travel slowly eastward, and this seems to be the case in regard to the use of nitrous oxide as an anæsthetic. In this country it is administered by dentists at almost every cross-road, and so freely—we might say recklessly—that it seems fair to infer that its inhalation is without danger. In France, it appears, its benefits are almost unknown. A recent article by Aubeau, which appears in *l' Odontologie*, for Dec. 1885, and Jan. and May, 1886, is devoted to a mild defence of its employment by dentists. A detailed account is given of its use in 20 out of 58 cases of tooth extraction, in all of which the urine of the patient was examined carefully after the operation, without the detection of a trace of sugar.

The number of the same journal for May, 1886, contains an interesting article by Hugenschmidt, a recent graduate of the Dental Department of the University of Pennsylvania, in which an excellent account is given of the free way in which nitrous oxide is used in the United States. In contrast to the few cases studied by Aubeau, Hugenschmidt mentions three American dentists who have administered the gas more than 300,000 times, and describes very well the method of its administration in this country, which has been so brilliantly successful. All this, however, seems too much for Aubeau, who adds to his *confrère's* article a note, in which he says that he can neither imitate nor approve the audacity of our countrymen, although their experience shows that "the use of nitrous oxide does not involve very formidable dangers." This conservative opinion does more credit to the prudence than to the enterprise of our French brethren, who seem to need just such information as is furnished in our American schools of dentistry, and as can be gathered from observation of the general practice in this country.

TAMPERING WITH THE QUARANTINE LAWS.

Notwithstanding the provisions for the closest scrutiny of vessels entering the Delaware, a case of deliberate infraction of the quarantine laws has taken place which wellnigh escaped detection. The captain of the Norwegian brig, "Grid," who permitted agents of a commission house to board and remain on his vessel in violation of law, and denied the act at the official inspection at the Lazaretto, deserves more than a reprimand. His prompt conviction before the court and the imposition of a fine and the payment of the costs of prosecution were fully merited.

The fact that the vessel was free from cases of sickness does not modify the gravity of the offence. The law distinctly prohibits all intercourse with vessels before an investigation by the Lazaretto officials, and unless it is rigorously enforced quarantine regulations are little more than a farce. It is to be hoped that this example of the vindication of the law will encourage its officers to renewed vigilance, and hereafter deter officious persons from tampering with the health regulations of the port.

REVIEWS.

Organic Materia Medica and Therapeutics. By James Young Simpson. Small 8vo. pp. 350. New York: J. H. Vail & Co., 1885.

This little book of 350 pages contains much to commend, and little to condemn. It essays to give a concise and condensed idea of the origin, natural order, habitat, synonyms, solubilities, preparations, general physiological and therapeutic action of each organic drug in the materia medica. In some instances the chemical tests and toxicology are also added. It embodies an account of a number of therapeutic agents which occupy a very prominent position in the armamentarium of some of our ablest practitioners, but which are only noted for their absence in our standard and more pretentious works on therapeutics. It is clear that our indigenous remedies merit a more prominent position than they at present occupy, and it is, therefore, pleasing to find many of them discussed in the general plan of this work. Among the most noteworthy of this class will

be found apocynum, bryonia, calendula, cannabis Americana, castanea, chimaphila, gossypium, phytolacca, pulsatilla, rhus glabra, salvia, sambucus, viburnum, etc. It contains some valuable hints on hypodermatic medication, and, with a few exceptions, it is brought down to the present time, and fulfils the aim of a work written "for ready reference on the organic materia medica." For the teacher it is as well adapted as for the student.

SOCIETY PROCEEDINGS.

THE AMERICAN OTOLOGICAL SOCIETY.

Nineteenth Annual Meeting, held at New London, Conn., July 20, 1886.

(Specially reported for The Medical News.)

Morning Session.

The President, J. S. Prout, M.D., of Brooklyn, called the Society to order.

Dr. S. Sexton, of New York, read a paper entitled

ACUTE AND CHRONIC PURULENT INFLAMMATION OF THE MIDDLE EAR TRACT, AND THEIR COMPLICATIONS.

It was based on the records of 2366 cases, which were divisible into three classes: acute purulent inflammation of the middle ear (739 cases); acute catarrhal inflammation of the middle ear (245 cases); and chronic purulent inflammation (1382 cases). The consideration of acute catarrhal inflammation was included in the consideration of acute purulent inflammation, since in the beginning the conditions were probably the same, although not always going on to suppuration. Out of this series of cases, 131 were selected on account of their gravity. Of this number, there were 12 deaths.

In no disease of man is a knowledge of regional anatomy more important than in disease of the middle ear. The speaker then gave a thorough *résumé* of the anatomy of the temporal bone, accepting the description of Prof. Leidy as the most satisfactory. The temporal bone at birth is peculiar, in the fact that the tympanum and mastoid antrum are about as large as they ever become in adult life. The petroso-squamosal suture is imperfectly closed.

The symptoms were next referred to. Brain symptoms, such as headache, vertigo, pain, delirium, nausea, and vomiting may occur, in consequence of middle ear disease without lesion of the cerebral structure.

The prognosis of purulent inflammation of the middle ear is favorable when non-meddlesome treatment is adopted, both as regards life and the preservation of hearing. Out of 20,000 cases of ear disease, where the patient had been seen at the beginning of the attack, no fatal case has occurred. Cases which have come under observation after severe symptoms have appeared have given 12 deaths. Some of the fatal cases occurred long after the ear trouble had abated.

In regard to treatment, he recommended incision of the drum-head. Trephining of the mastoid process has been advised by some authorities. Dr. Sexton took up a consideration of the indications which have been regarded as calling for the application of the trephine, and held that they were insufficient. From his experience he was led to believe that drainage could be best maintained through the natural channel.

Dr. Sexton also described

A NEW OPERATION FOR THE RADICAL CURE OF CHRONIC PURULENT INFLAMMATION OF THE MIDDLE EAR TRACT.

Since describing a form of chronic purulent inflammation of the attic in a paper read before the Society last year, it had occurred to him that something might be done with these cases by means of an operation. It seems especially desirable to cure these cases, when the ear remains simply a reservoir for purulent matter, liable at all times to infect the system. It is found, in the greater number of these cases, that the remaining portion of the conducting mechanism no longer serves to aid in the transmission of sound, but acts rather as an obstruction to drainage. Where the membrana flaccida and a portion of the ossicular chain only remain, the former often becomes thickened and everted, forming with the altered mucous membrane a pouch for the retention of putrescent matters which may slowly escape. Where granulation tissue or polypoid growths are present in the attic or antrum, the escape of secretions is still further interfered with. This produces long-continued and great irritation.

The author has observed that in a number of cases where the transmitting mechanism had been lost, a spontaneous cure followed; and it occurred to him that the curative action of nature might be imitated with advantage. Where drainage from the attic and antrum is interrupted, a cure can only be assured by an operation permanently clearing the passage outward from the tympanum.

Last year the operation was tried on a long-standing case of otorrhœa, due to chronic purulent inflammation of the attic. In order to avoid the danger of using an ordinary lamp in connection with the administration of ether, an electric light was used. The operation has since then been fully performed in several cases.

The first step of the procedure is to separate the membrana flaccida from the edge of the auditory plate and to remove any portion of the membrana vibrans adherent to the auditory ring. If the malleus and incus remain *in sitû*, it is well to divide the tendon of the tensor tympani muscle when present, where it leaves the handle just behind the short process and below the chorda tympani. The chorda tympani, when remaining, is then divided where it enters the tympani at the pyramid and also at its exit into the canal of Huguier The long process of the malleus, being also received into the glenoid fissure by means of this short oblique canal, along with the chorda, may be more or less detached at the same time. The detached tissues and ossicles should now be removed with the forceps. It will frequently be found that the incus, having been displaced, still remains. It may be removed with the attic scraper, which is to be introduced from below and passed up along the inner wall of the tympanum, when the distal extremity may be carried over the incus or malleus, if the latter bone remains, and by traction the ossicles can be detached. Polypoid masses, granulation tissue, and the products of inflammation may now be removed with the cutting curette or cutting forceps, and the parts dressed with a four per cent. solution of cocaine to relieve pain. There is usually free bleeding during the operation, often sufficient to protract it and increase its difficulties.

The effect of injury or destruction of the chorda tympani nearly always manifests itself in some way, but had never, in his experience, been a matter of serious import. Disturbances of taste sometimes follow the operation, but they gradually disappear and leave the sense of taste unaffected.

The drum should be well cleansed, and light dressings of boracic acid applied until healing takes place. The salicylic acid powder may be applied as freely as can be borne. In some cases this is irritating at first, but tolerance is soon established. It may then be kept up until the parts cease to discharge.

In the cure resulting from this treatment, a dermic transformation of the tympanum takes place; but mucus may occasionally gain admission from the Eustachian tube during recurrent head catarrh or on blowing the nose. This should be frequently removed with cotton-wool, and, if necessary, the drying applications renewed for a time. Where the incuso-stapedial connection remains he should not hesitate to perform this operation, unless a very considerable portion of the membrana vibrans is present. The instruments employed and some of the diseased ossicles removed were exhibited.

DR. C. R. AGNEW, of New York, said that he inferred from the speaker's remarks that he objects to the opening of the mastoid.

DR. S. SEXTON replied that he never had any difficulty in obtaining drainage in cases of periostitis externa by a free incision with a small tenotomy knife.

DR. AGNEW held that where the inflammation involves the mastoid cells, some portion of the external wall of the mastoid should be removed. The objection to the trephine is that it does not expose a sufficient area of the cancellated tissue of the mastoid. He did not see how the new operation which had been described will be of service in these cases.

DR. SEXTON said that the new operation was recommended in only chronic cases.

DR. H. KNAPP, of New York, said that the upper tympanic pneumatic cells resembled, to a certain degree, the frontal sinuses. They have a direct natural drainage through the infundibulum into the nose. When this is closed by disease, the lateral part of the sinus over the orbit dilates and the cavity is more easily reached and more effective drainage is obtained by opening the sinus from the orbit. In a like manner, we obtain in most cases easier and more effective drainage of the supratympanic cells by opening the mastoid cells with which they communicate.

DR. A. H. BUCK, of New York, then read a paper on

PAINLESS AND ONLY SLIGHTLY PAINFUL ULCERATION OF THE MEMBRANA TYMPANI, PROBABLY OF A TUBERCULAR NATURE.

Its object was to call attention to the features by which the early stage of tubercular disease of the membrana tympani could be recognized. Three cases had been seen by the author. The patients were in a condition of fair general health; one of them had disease of the vertebræ. No evidence of pulmonary disease was found in either of the three cases. Tinnitus and slight impairment of hearing were the first symptoms noticed.

In two of the cases which were examined at an early period, there were slight redness and swelling at the upper part of the membrana tympani and of the skin covering the bony wall. In a short time the infiltration extended into the entire posterior superior quadrant. The membrane became bulging and at the most prominent point a perforation established itself.

In the incipient stage, the distinguishing features are the tendency to localization in the upper posterior portion of the membrana tympani, the marked insignificance of the pain or even its entire absence and the intolerance to all but the simplest local measures.

DR. E. GRUENING, of New York, had seen a number of cases in which he was led to infer that the ulceration of the drum-head was due to tuberculosis. In one case, that of a young man, there were two openings in the inferior posterior quadrant of the drum-head. There was very little purulent discharge. The fact that there were two openings showed that the condition was not the result of perforation from accumulation. It appeared to be a melting-down process. In another case there were multiple openings, so that the membrane appeared to be honeycombed. These cases improved under treatment, but the openings remained.

DR. C. R. AGNEW had seen a number of cases which he considered to be tuberculous in character. He related the case of a young man with phthisis affecting the apices of both lungs. He stated that a short time previous he had begun to have slight ringing and a sense of dulness in the ear, that this had gone on for two or three days and then, when blowing his nose, he found that he whistled through his ear. In the ear complained of, there was an opening looking as though it had been made by a punch. The opening was elliptical. Within a few days the same thing occurred in the other ear.

DR. J. A. ANDREWS, of New York, stated that he had examined a large number of cases of middle ear trouble occurring in phthisical subjects, and some with a great deal of care, but had never found the bacillus tuberculosis.

DR. A. H. BUCK thought the failure to find bacilli did not exclude tuberculosis, for their chances of escaping detection are numerous. He had seen cases like those described by Dr. Gruening, but not in the early stages, and had, therefore, not considered them in his paper, as there was a possibility that they were due to previous ear disease.

DR. J. ORNE GREEN, of Boston, had been much interested in this paper, and recognized several characteristics which he applied to tuberculosis. The destruction coming on without pain and without discharge is very significant of the tubercular diathesis. He agrees with the speaker that in treating these cases only the very mildest measures can be used. Strong applications make the trouble worse. Twice, in cases of advanced tuberculosis, he had seen, on examining the drum membrane, little white glistening points about tne size of a pin-head, not secreting at all, and in one case with no congestion. In both cases the spots disappeared in a few days, and within twenty-four hours there was a clean punched-out opening in the drum membrane. This occurred without any discharge. He attributed this to isolated tubercles in the tissue of the drum membrane.

DR. A. H. BUCK, of New York, then made some remarks on

CERTAIN TECHNICAL DETAILS RELATING TO OPERATIONS ON THE MASTOID PROCESS.

He first referred to the objections which had been made to the drill. It had been stated that there is danger of plunging the drill into the lateral sinus, or even into the brain; he had, however, found no tendency for the drill to go astray. It had been said that the opening made was too small, but any sized drill might be used; he uses a drill one-fourth of an inch in diameter until the antrum is reached, and finishes the operation with a smaller drill. This gives a sufficient opening for drainage. When there is a large sequestrum, it is necessary to make a larger opening. After the use of the drill pyæmia and septic fever are rare. With a knowledge of the part to be operated upon, the drill may be used with perfect safety. It can be guided perfectly by resting the fingers on the bone. The conical shape of the drill also enables the operator to tell when its point has entered a cavity.

The objections to the use of the chisel were next taken up. When this is used the wound in the adjacent soft part must be larger, and the opening in the bone is more extensive, leading to a depressed cicatrix; more time is required in the operation, and it is not free from danger. These objections are, however, trifling, if the results of the operations are found to be more satisfactory than those following the use of the drill. A study of the statistics of both methods seems to show that there is nothing to warrant the statement that chisels and gouges are to be greatly preferred to drills in establishing opening into the mastoid process.

In operating with the drill, after making the opening, the author cuts out a little canal for the escape of the discharges, for the opening made by the drill is covered by the flap when it comes into position. For the first four or five days after the operation, the wound is irrigated once a day with a bichloride solution (one to two thousand).

Dr. Buck, in reply to a question, said that in his earlier operations he applied the drill a short distance in front of the vertical line. His present plan is different; a straight vertical incision three inches long is made; by this means he exposes the mastoid process where it curves into the meatus; the drill is then applied to the first flat surface. The only difficulty is in establishing the final communication between the canal and the antrum.

DR. J. ORNE GREEN said that he uses the drill almost entirely. He prefers to make a small opening at first, and is then guided by what is found. Some cases require a large opening, and in such cases the gouge and chisel will come into play; in the majority of cases a small opening is sufficient. In some of these cases the use of the dental engine is very applicable. He employs a modification of the engine, which may be screwed to a table; it is turned by a handle, and any one can furnish the power; no skill is required as in the engine worked with the treadle. Used in this way, the engine is of great service. The burrs can be used with the greatest delicacy. He uses a drainage tube, and keeps it in as long as possible.

DR. H. KNAPP, of New York, advocated the use of the chisel. In his first operations he used a drill, but had abandoned it. With the chisel one can at every step observe the condition of the tissue which he is cutting; with the chisel one has a perfectly smooth surface, rendering it easier to cleanse the wound; it is also very easy to manage the chisel. The principal reason in favor of it is, however, that it enables each step of the operation to be seen.

DR. H. D. NOYES, of New York, said that there is much less danger in the use of the chisel than of the drill. There is often great difference in the anatomical relations of the parts. The lateral sinus is not always found in the same place. With the drill there is danger of perforating the wall of the sinus, or of some important vein; with the chisel or the gouge one can explore the part, layer by layer, and ascertain how the parts are situated. This is a strong argument in favor of this instrument.

DR. J. A. ANDREWS, of New York, stated that in his operations he always used the chisel, but had always begun with the drill. He believed that the chisel is the best instrument, and can be used with more caution than the drill. He always makes a large opening, for he believes that a collection of pus should always be given free vent. Instead of the ordinary drainage tube, he uses a small rubber gutter to keep away the soft parts.

DR. E. GRUENING, of New York, stated that he had opened the mastoid process seventy-seven times. At first, he used the drill, and in acute cases the results were all that could be desired. The drill is, however, not applicable to all cases and he had since used the chisel. A small opening may be made with the chisel. What can be done with the drill can be done with the chisel.

DR. A. H. BUCK, of New York, remarked that from the direction which the discussion had taken it might appear that he was in antagonism with the chisel. He was not in antagonism with the chisel in those cases where a large portion of bone is to be removed. He left those out of consideration in his paper. Where a large mass is to be removed, it cannot be removed with the drill. The two instruments cannot come into conflict.

A communication in reference to the organization of

A CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS,

was presented and referred to a committee consisting of Dr. C. R. Agnew, Dr. H. Knapp, and Dr. John Green, to consider and report at the evening session.

EVENING SESSION.

DR. H. KNAPP, of New York, narrated the

FATAL TERMINATION OF A CASE OF SCLEROSING MASTOIDITIS AFTER CHISELLING OF THE BONE.

A man aged fifty years, had extensive suppuration in both ears after scarlet fever in childhood. The right ear became totally deaf, and the left, very hard of hearing, became deaf (hearing reduced to a quantitative perception of sound) by a recent attack of dizziness. Dr. Knapp found both tympanic membranes absent, the cavities sclerosed in both, pale in the right but congested in the left ear. Behind the left ear was found a cavity fully an inch deep, lined with immovable skin, the re-

sult of former exfoliation of bone. Three weeks later facial paralysis on the left side occurred. It disappeared in two weeks, under steaming and large doses of iodide of potassium. Two weeks later, the patient suffered with constant headache and nausea. The mastoid was opened to the depth of half an inch by chiselling. The bone was compact and very vascular. During the first two days the patient was sleepy; could not be aroused on the third, and died comatose on the fifth. No autopsy was allowed.

Death was due to traumatic meningitis. In regard to opening the bone in sclerosing mastoiditis, the prognosis is good when the sclerosis is the result of catarrhal or plastic inflammation, but bad when it is the consequence of old caries or necrosis. There are cases on the border-line, and even when the prognosis is bad, the indications may be strong. The operation will rescue a certain number of otherwise fatal cases.

DR. O. D. POMEROY, of New York, reported

A CASE OF ABSCESS OF THE MASTOID CELLS IN WHICH THE CHIEF INDICATION FOR OPERATION WAS ELEVATION OF TEMPERATURE.

A. S., aged twenty years, fairly robust, had a violent attack of otitis of the right ear which came on January 30, 1886. The following morning there was free discharge. February 1 he entered the hospital, when a large perforation was found; a poultice and warm douches were ordered. By February 4 the membrane looked almost normal. There was some pain in the occiput and a temperature of 103.6°. Ten grains of quinine with twenty grains of iodide of potassium, to be repeated in three hours, were ordered. This was followed by a reduction of two degrees in the temperature. The following day the temperature again went up, and it was apparent that a purulent process was going on. There was no swelling over the mastoid, and the pain was no greater than might be expected from a neuralgic condition. After consultation it was decided to open the mastoid process. A drill was introduced and from four to six drops of pus evacuated. After the operation the patient continued to improve until he was discharged cured.

DR. J. A. LIPPINCOTT, of Pittsburg, referred to a recent case in which a similar operation resulted in failure. Something over two years ago he operated in a case of sclerosing mastoiditis which had been suffering intense pain for twelve months, and which did not yield to alterative and tonic treatment. After the operation the patient remained well for thirteen months. The pain then returned and continued in spite of all treatment. Last March a second operation was performed, and a larger opening with the drill made. No benefit was produced.

DR. H. KNAPP stated that the cases which he had reported, where relief followed chiselling open a sclerosed mastoid, have remained well.

DR. CHARLES H. BURNETT, of Philadelphia, presented a paper

ON TWO CASES OF CHRONIC PURULENT INFLAMMATION OF THE ATTIC OF THE TYMPANUM, WITH PERFORATION OF THE MEMBRANA FLACCIDA, TREATED WITH PEROXIDE OF HYDROGEN.

In the first case no application had had the same good effect as the peroxide of hydrogen. Every other medicament had seemed to irritate rather than heal the inflamed mucous membrane. In the second case, the discharge, which had been very chronic, was promptly checked by the use of the peroxide of hydogen.

The chemical formula of this drug is H_2O_2, and by its affinity for albuminous matters, especially those of pus, it seeks every particle of this matter in a cavity like the middle ear, and thoroughly cleans the parts. The union with pus is shown by a copious foam, which boils out of the external ear; when the foaming ceases, and the peroxide returns clear, the diseased cavity has been thoroughly cleansed. In many cases this seems sufficient to effect a cure. Where there is a perforation in the membrana flaccida, the application is made by means of the tympanic syringe, the long and slender nozzle of which is introduced through the perforation at the attic of the tympanum. The peroxide is used undiluted.

DR. WILLIAM S. LITTLE, of Philadelphia, read a paper entitled

IN THE PHYSIOLOGY OF HEARING IS THERE AN OVERLAPPING OF EACH AUDITORY FIELD THE SAME AS IN BINOCULAR VISION?

Cases of one-sided deafness afford the opportunity of mapping out the auditory field for one ear, and it is found that with the watch at two feet from the ear, the tick can be heard about ten or fifteen degrees across the median line of the head. This gives more scope to hear sounds produced on the side of the head opposite the good ear. The tuning-fork is not heard even up to the median line on the side of the ear tested. The watch has been used in making the observations. If the field of one ear reaches beyond the median line to about ten degrees, we have, when both ears are normal, an overlapping of each field to the extent of fully ten degrees on either side of the median line in front, above, and behind the head. Each ear hears sounds in this area of twenty degrees. Outside of this area each ear hears singly. By means of this there is no need to turn each ear toward the source of sounds which reach the individual; the direction of sound is best found in this way for safety in walking, and maintaining the erect position. Sudden loss of hearing on one side puts the sufferer to great annoyance, as the ability to determine the direction of sounds is, in a measure, lost, the patient often looking in the wrong place when called. It is fully as perplexing, if not more so, than in a case of sudden loss of sight in one eye, making seeing dependent on one organ of vision.

The attempt to restore hearing should be directed, not only to obtain hearing in a line directly in front of the ear, but also to increase the area of hearing in the affected ear, or in both affected ears, till it reaches, if possible, the coalescence seen in normal ears.

The literature of the subject of audition and otology does not give any information on this point; too close a comparison between the eye and the ear cannot be made. The auditory and optic nerves respond to very different stimuli. The auditory nerve has no commissure or decussation of fibres like the optic, and has a less central position in the cerebrum.

DR. GORHAM BACON, of New York, read by title a paper on *Two Cases of Ear Disease due to Traumatism.*

The Society then went into

EXECUTIVE SESSION.

The proposition with reference to the organization of

A CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

was discussed, and favorably voted upon, and the following were appointed the Committee of Conference: Drs. C. R. Agnew, of New York; H. Knapp, of New York; John Green, of St. Louis; W. H. Carmalt, of New Haven; and George Strawbridge, of Philadelphia.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. J. S. Prout, of Brooklyn.

Vice-President.—Dr. Samuel Sexton, of New York.

Secretary and Treasurer.—Dr. J. J. B. Vermyne, of New Bedford, Mass.

Committee on Membership.—Drs. Gorham Bacon, W, S. Little, and E. W. Bartlett.

The following new members were elected: Dr J. B. Emerson, of New York; Dr. J. O. Tansley, of New York; Dr. J. L. Minor, of New York; Dr. Henry L. Morse, of Boston; Dr. Huntington Richards, of New York; and Dr. T. Y. Sutphen, of Newark, N. J.

The Society then adjourned.

THE AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-second Annual Meeting, held at the Pequot House, New London, Conn., July 21 and 22, 1886.

(Specially reported for THE MEDICAL NEWS.)

WEDNESDAY, JULY 21.—MORNING SESSION.

THE PRESIDENT, DR. WM. F. NORRIS, of Philadelphia, called the Society to order.

A communication with reference to the organization of a

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

was read, and referred to a special committee for consideration and report.

DR. H. KNAPP, of New York, then read a paper on

PYOGENIC MICROÖRGANISMS, WITH DEMONSTRATIONS AND EXPERIMENTS.

He made some general remarks with reference to the dependence of suppuration on certain kinds of microorganisms, the pyogenic bacteria, of which pure cultures had been obtained during the past two years. He exhibited these bacteria in numerous test-tube specimens on agar-agar, and also under the microscope. He also exhibited slides of different tissues of the eyes that had been infected with these germs. He showed two rabbits which he had operated on the day before for cataract, in the presence of members of the Society. Extraction had been made on the left eyes with clean instruments, and on the right eye with instruments contaminated with staphylococcus pyogenes aureus. The left eyes were free from secretion; the right eyes discharged matters profusely, and were in a state of destructive inflammation. He then operated on the other rabbits in the same way.

The four rabbits were exhibited the next day. The right eyes in all were suppurating; the wounds of the left eyes in three of the rabbits were in good condition. In one of the first two rabbits it was suppurating. This eye had become infected from the right eye of the other rabbit. They had been kept in the same box, and the operator had found them with their heads in contact.

In reply to a question as to the best method of cleaning instruments, Dr. Knapp said that in the institutions in Europe the instruments are placed in an antiseptic solution. This, however, has the disadvantage of dulling the edge of cutting instruments. His experiments had shown him that simple washing with water in the case of smooth instruments, followed by friction with a clean towel, renders them bacteriologically clean. Where an instrument has a groove, or is at all rough, it is much more difficult to clean. Instruments like forceps may be put in the antiseptic solution. It must be remembered that in the majority of our operations a certain quantity of infecting material is required to produce any effect. Where there is a free escape of liquid from the wound, the material is washed off; but where there is a sucking-in process, the danger is much greater.

DR. B. E. FRYER, of Kansas City, remarked that there was one antiseptic, lately come into use, which would probably not interfere with the edge of cutting instruments—that is hydro-naphthol. It has, however, not been sufficiently long under observation to enable us to say whether or not it will completely sterilize instruments. He suggested that chloroform would probably perfectly sterilize instruments.

DR. HUBBEL, of Buffalo, asked Dr. Knapp whether there were not certain conditions of the eye which favored infection of the wound after operation. He had recently, in a case of cataract in a man sixty years of age, operated where there had been a long-standing purulent inflammation of both conjunctivæ. He performed an iridectomy, following it in two weeks with extraction. Both operations were entirely successful and without accident, notwithstanding the fact that there was a constant purulent discharge, The only antiseptic used was a solution of boracic acid.

DR. H. KNAPP thought that a lachrymal discharge with a certain amount of conjunctivitis furnishes a favorable soil for the growth of bacteria. In operating in such cases, the discharge should be completely removed. A certain quantity of the pathogenic bacteria is required to produce infection. He had pricked the cornea to one-third or two-thirds its depth, and covered the wound with an emulsion of the bacteria. In only one out of every four or five did abscess develop.

DR. J. A. ANDREWS, of New York, said that he had frequently pricked the cornea and applied the staphlococcus pyogenes aureus, and had repeatedly seen recovery follow without suppuration or inflammation. Mere contact of the microbe with the wound is not always sufficient to produce suppuration, especially in the case of the cornea, where the discharge is liable to be washed off. Where the material has been introduced into the wound and kept there for a short time, he had never seen a failure.

In the cleaning of instruments, he used what he termed an aseptic fluid. It consists of clean water boiled some time. The principal value of antiseptic solutions in hospitals is that they furnish something one is sure is clean. Water is not always clean. He does not use boiling water in washing instruments; the water is boiled to render it aseptic.

Dr. C. S. Bull, of New York, presented

AN ANALYSIS OF ONE HUNDRED CASES OF EXUDATIVE RETINITIS OCCURRING IN THE COURSE OF BRIGHT'S DISEASE.

Only such cases were included in the report as had been examined by the writer and had been followed to their termination. All cases due to scarlatina or pregnancy were excluded. Out of 500 cases examined, only 108 fulfilled these conditions. The ophthalmoscopic examinations were made by the author, and the urine was always examined. In 54 of the cases, both eyes were affected when the patient came under observation, and in 93 per cent. both eyes were ultimately involved. Hemorrhages occurred in 69 cases. In 34 cases there were no hemorrhages. The hemorrhages were intimately connected with disease of the bloodvessels. Only one instance of color affection was observed.

The prognosis with reference to the duration of life is very unfavorable. The 113 cases reported were collected during a period of thirteen years; of this number 86 have died, 57 during the first year and 12 during the second year; 17 were still living, but 14 of these presented themselves within the last six months. One of these cases, however, was seen for the first time seven years ago. A rather unusual complication was seen in four of the cases. That was the presence of sugar as well as albumen in the urine. The amount of sugar was variable.

Dr. E. Gruening of New York, had collected over one hundred cases of this affection, and he found that none of them had lived over two years after the diagnosis of retinitis albuminurica had been made. In this class of cases he has included only those in which the typical stellate changes were seen in the maculæ of both eyes. He lately had seen this appearance in the macula of one eye in a patient who presents no evidence of Bright's disease. This was the first time that he had seen this exquisite change without signs of renal disease.

Dr. B. E. Fryer, of Kansas City, said that in these cases albumen is occasionally absent from the urine for a short time. In two such cases he had found that albuminose was present during the time that albumen was wanting.

Dr. David Webster, of New York, was satisfied that in rare instances these patients recover their general health and may live indefinitely. Some years ago he examined the eyes of a clergyman and found the typical appearances of retinitis brightii. He had been examined fifteen years previously, by a competent observer, who found the same condition and also found albumen and casts in the urine. The urine was examined and slight traces of albumen found.

Dr. O. F. Wadsworth, of Boston, said that where the retinitis albuminurica comes on during or immediately after pregnancy, he had seen the stellate spots in the maculæ entirely disappear. He had also seen typical stellate deposits in cerebral tumor and in what was supposed to be meningitis, but in which there was no albuminuria.

Dr. E. Gruening, of New York, said that the cases of retinitis brightii which are seen in private practice, differ very materially from those which are seen in hospitals. The patients who consult the oculist are usually those with the small contracted kidney, while the patients with the large, white kidney find their way to the hospital.

Dr. C. S. Bull, of New York, in closing the discussion, remarked, that he had excluded all cases where the albuminuric retinitis was due to scarlet fever or to pregnancy. He did not mean to say that the so-called stellate exudation in the region of the macula is typical of Bright's disease. He had seen it in intracranial tumor and in cases supposed to be meningitis. Retinal exudation other than stellate he had seen not infrequently in cases of large white kidney.

Dr. George C. Harlan, of Philadelphia, then reported a case of

THROMBOSIS AND PERIVASCULITIS OF THE RETINAL VESSELS.

The patient, a married woman, aged thirty-three years, came under observation June 5, 1886. Her father and a younger sister had died of Bright's disease, and her mother of paralysis. During the past two years she had had considerable headache. She had a miscarriage in July, 1881, from which her recovery was delayed. She had a second miscarriage, without special trouble, in January, 1886. There was no trouble with the eyes until May 7th, when she noticed dimness of vision in the left eye. This increased during the day, and the following morning there was only light perception in this eye. She was examined two weeks later by a surgeon, who pronounced the condition one of embolism. There was no suspicion of specific disease. There was no uterine trouble and the heart-sounds were normal. The urine had a specific gravity of 1.009, contained some albumen, but no tube casts were found. Examination of the eyes showed no light perception in the left eye. The media were clear. There were hemorrhages scattered through the retina. Some were striated, extending in long streaks along the vessels. There were three groups of white spots at the macula. With one exception, all the vessels of the retina were converted into white bands. The exception was a small artery having an independent origin. The vessels were of nearly normal size. Five or six weeks later, the hemorrhages had been absorbed, but there were no other changes. In the right eye there were several small hemorrhages and two filmy white patches; these subsequently disappeared. In July she had a slight attack of paralysis on the left side. Examination of the urine showed some albumen and hyaline tube casts. The rapid onset and the occurrence of blindness within a few hours, seemed to exclude the possibility of disease of the vessels. Embolism would not account for the condition. The speaker suggested that the partial blindness for the first few hours was due to hemorrhage, and that the complete blindness coming on later was due to thrombosis. Thrombosis of a whole series of vessels is, however, rare. Another possible explanation is that there had been, for some time, disease progressing in the outer walls of the vessels without giving rise to sufficient disturbance of vision to attract attention.

By way of comparison a second case was described, in which the affection seemed to be a perivasculitis. It was that of a negro woman who had been partially blind for a long time. The right eye was the seat of a dense

cataract. In the left eye V. $= \frac{20}{C}$. The lens was hazy and the disk pale. Extending upward, there was a large artery converted into a chalky band. Two smaller arteries exhibited the same condition in places.

Dr. William S. Dennett, of New York, then described

A NEW TEST-TYPE.

He called attention to the fact that, although for twenty-five years the schools of the civilized world had been under the observation of oculists, who all agree that great good would be done by periodical examinations of the eyes of scholars, and although such examinations are very simple, the internal inertia of existing institutions has always prevented any continued action on the part of the schools. Among the laity there is absolutely no knowledge of what normal eyes should be expected to see. A card was presented which was designed for the use of educational institutions. It contained one set of letters, and a statement underneath of the exact distance at which these letters should be seen. The desire was expressed that this, or some similar card, should be placed on the wall of every schoolroom in a conspicuous place, so that it should become of necessity a familiar object and a standard of measurement that would be remembered through life.

Dr. Hasket Derby, of Boston, read a paper on

THE POSSIBLE RETARDATION OF RETINITIS PIGMENTOSA IN THE YOUNG.

This affection is, as a rule, considered incurable, leading gradually to complete blindness. In America the disease is exceedingly infrequent, the author having seen it but 27 times in 13,000 eye cases. In 1881, a boy, three years of age, was brought to him from Western Virginia. It was observed that toward night vision diminished. There was no history of blindness in the family. Five years later he came again, accompanied by his sister, seven years of age. Both children were night-blind, and presented the evidences of retinitis pigmentosa. Under the use of the constant current, there was improvement. A similar case of improvement under the use of the constant current, under the care of Dr. Standish, was reported.

The object of the paper was to invite discussion as to the use or non-use of such eyes for educational purposes, and as to the possibility of adopting measures for delaying the progress of the organic change.

A third case, that of G. W., aged fourteen, was described. He presented the typical appearances of retinitis pigmentosa. Non-use of the eyes and the application of the constant current were recommended. He was subsequently advised by others to use the eyes freely. In five years vision diminished from three-tenths to one-tenth. This rapid progress of the disease, it was thought, might have been aided by the use to which the eyes had been subjected.

Dr. William S. Little, of Philadelphia, reported one case of retinitis pigmentosa occuring in a deaf-mute, in which decided improvement in vision took place under the use of the faradic current. The improvement continued for two years without change. He then went West and seven years later he was doing well, but he could not see quite as well at night as before.

Dr. L. Webster Fox, of Philadelphia, had treated a number of cases successfully. He had found that it was the negative pole that produces the good results. He also noted that if there was no enlargement of the field after three applications, improvement was not to be expected. In all the cases in which improvement took place, the bloodvessels seemed to increase in calibre, and the night-blindness correspondingly diminished.

Dr. George C. Harlan, of Philadelphia, had recently seen two well-marked cases of this affection; one in a boy of seventeen years, and the other in his sister a few years older. His faith in any form of treatment being weak, he advised that the eyes be used as long as sight remained. From his experience he was led to believe that there is likely to be a culmination of the disease about puberty.

Dr. George Strawbridge, of Philadelphia, said that he had tried the use of electricity in this affection thoroughly some ten years ago. He did not obtain benefit in a single instance, and placed more reliance upon the occasional use of alteratives, as bichloride of mercury and iodide of potassium, looking on these cases as probably of syphilitic origin.

Dr. Samuel Theobald, of Baltimore, had seen temporary improvement from the continued use of phosphate of iron, quinia, and strychnia. One of these cases was seen some ten years ago, when eight years of age; he retains sufficient vision to enable him to perform his duties as a travelling salesman. There was no intermarriage of the parents of this patient, but there was a history of a similar trouble in other members of the family.

Dr. S. D. Risley, of Philadelphia, remarked that it had seemed to him that, with the hypodermatic use of strychnia, he had secured improvement in the central sharpness of vision. He had frequently seen improvement follow the use of this drug, but, so far as he knew, it had never been permanent. As regards the age at which the affection may develop, he had seen it occur under five years of age, in two children of the same family.

He reported the case of a young man with retinitis pigmentosa, with marked contraction of the field, and asthenopia principally due to hypermetropic astigmatism. He was treated with alterative remedies for two years, during which time the difficulty had not materially increased. To relieve the asthenopia a weak solution of eserine, sufficiently strong to contract the pupils without causing peri-orbital pain, was ordered, and under its use vision decidedly improved. He has used this solution more or less constantly for the past two years, and finds that when he is without it, he is distinctly more uncomfortable.

Dr. O. F. Wadsworth, of Boston, referred to a case which, in connection with those reported, shows the variable course the disease may pursue when left to itself. A young man, twenty-four years of age, a divinity student, was seen in 1873 presenting typical retinitis pigmentosa so far as the opthalmoscopic appearances were concerned. He had well-marked night-blindness. He continued his work, and when seen eight years later, vision was about the same, but the visual field seemed to have decreased to a slight extent.

DR. EDWARD JACKSON, of Philadelphia, read a paper on

THE EQUIVALENCE OF CYLINDRICAL AND SPHERO-CYLINDRICAL LENSES.

It was intended to demonstrate the laws of such equivalence, showing that equal crossed cylindrical lenses are optically equivalent to a spherical lens of the same refractive power. Crossed cylinders of unequal refractive power may be regarded as crossed cylinders of equal refractive power combined with a third cylindrical lens, or, as their equivalent, a spherical combined with a cylindrical lens. It was proven that any two cylindrical lenses with their axes placed obliquely the one to the other, might be represented by crossed cylinders—that is, cylinders with their axes perpendicular to one another, or by their equivalent in the shape of a sphero-cylindrical lens; hence that any number of cylindrical lenses with their axes placed in different directions are optically equivalent to a single sphero-cylindrical lens. To determine the sphero-cylindrical equivalent of any two cylindrical lenses, construct a parallelogram, two sides of which are proportional to the refractive power of the given lenses, the angle included by those sides being double the angle made by their axes. Then the diagonal which cuts this included angle will be proportional to the cylindrical portion of the desired equivalent; and to get the spherical portion it is only necessary to subtract one-half of this cylindrical equivalent from half the sum of the cylinders given.

DR. WILLIAM S. LITTLE, of Philadelphia, in speaking with reference to the practical side of this question, said that in about one-half of his cases of mixed astigmatism the patients have preferred crossed cylinders to their equivalent sphero-cylinders. In using a sphero-cylinder it is essential that it be accurately centred.

The committee to whom was referred the consideration of the proposition with reference to the organization of a

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS,

reported the following resolutions, and recommended their adoption:

Resolved, That a committee of five be appointed by this Society, and be authorized to confer with committees from other medical societies with regard to the organization of a convention or congress of such societies, and report at the next meeting of this Society.

Resolved, That it is the sense of this Society that its welfare would be put in peril by any alliance or coöperation which would interfere with its autonomy or independent meeting.

These resolutions were adopted, and the following committee was appointed: Drs. O. F. Wadsworth, of Boston; C. S. Bull, of New York; George C. Harlan, of Philadelphia; Samuel Theobald, of Baltimore; and B. E. Freyer, of Kansas City.

AFTERNOON SESSION.

DR. GEO. STRAWBRIDGE, of Philadelphia, reported

263 CASES OF CATARACT EXTRACTION WITH PARTICULAR REFERENCE TO THE AFTER-TREATMENT.

Two hundred and twenty-three of the above cases had never been reported. The operation was performed by the modified flap extraction, in which the incision lies midway between the old Gräfe incision and the corneal flap incision. It avoids the risks of both of these methods, and gives a sufficiently large opening. An iridectomy in an upward direction was always performed. Formerly the lens was removed by pressure with the spoon directly on the cornea, but fearing injury to that tissue, during the past year pressure with the finger on the closed eyelid had been substituted. The results had been as follows: Successful cases, 85.2 per cent.; partial successes, 8.1 per cent.; and failures, 6.7 per cent. Those cases were classed as failures in which fingers could not be counted at a distance of one or two feet. In twelve cases absolute loss of the eye occurred. These were, with one exception, lost by choroiditis. The other case was lost by choroidal hemorrhage.

After the operation the eye was thoroughly cleansed, and for the past two years a solution of boracic acid (two per cent.) had been employed. The speaker's former plan had been, after applying a bandage, to put the patient to bed in a darkened room, keeping him in bed for four to six days. Two-thirds of the cases had been treated in this way. He had found this plan exceedingly debilitating in elderly individuals, and during the past eighteen months he had gradually given it up, so that during the past six months the patients were, practically speaking, kept in bed only twenty-four hours. The room is as light as any ordinary room. The first element in the treatment of old people is to make them comfortable. If, at the end of twenty-four hours, everything is doing well, the patient is allowed to move about the room. No unsatisfactory result had followed this plan.

The speaker had employed in some cases cocaine. In one case, in which a four per cent. solution was used, a violent purulent inflammation began within twenty-four hours and resulted in total loss of the eye. Subsequently he had employed it without unpleasant results. His plan is to use a two per cent. solution, drop in one drop, wait a minute and drop in a second drop, and use only two drops. As much anæsthesia as is desirable is thus obtained. He had never employed any antiseptic except the two per cent. solution of boracic acid, and while this does no harm, he though that it did little good. He attaches much importance to stimulation after the operation. In elderly people the use of whiskey is begun a few hours after the operation.

DR. H. KNAPP, of New York, read a paper on

CATARACT EXTRACTION WITHOUT IRIDECTOMY.

Of the new operative measures which he had seen in Europe there were two above all others which he thought worthy of being tried; one was extraction without iridectomy, and the other, advancement of Tenon's capsule. Of the fourteen cataract extractions which he had made since his return, the last six had been without iridectomy. Three of these had made ideal recoveries, no reaction, clear, central, movable pupil, neither an anterior nor a posterior synechia. The other three had more or less posterior synechia, leaving the pupil ragged and somewhat obstructed, yet the adhesions were simple, not spreading a pseudo-membrane over the area of the pupil. Vision was fair, and could be rendered excellent by a simple needling, if remaining insufficient.

He followed Panas in the performance of the opera-

tion, large section along the upper margin of the cornea, free laceration of the capsule, expulsion of the cataract and its remnants, reduction of the iris with a probe if it did not occur spontaneously. Before the operation the eye is fully cocainized, the lids and conjunctival sac washed and sterilized. The instruments and hands are treated in the same way. After the expulsion of the lens, a small quantity of an antiseptic is injected into the anterior chamber along the whole section and eserine instilled into the conjunctival sac. The speaker believed that the chief advantage of this operation lies in the possibility of keeping the wound perfectly free from foreign substances, including portions of the lens, capsule, and iris. How often anterior and posterior synechiæ occurred, what the final visual results were, and how frequently after-operations would be required, were questions which could only be answered by extended statistics.

Dr. David Webster, of New York, presented a

REPORT OF FIFTY CASES OF CATARACT EXTRACTION.

In seventeen cases the operation was done under ether, in twenty-seven, under cocaine, and in six no anæsthetic was employed. The results were: Successes, 82 per cent.; partial successes, 12 per cent.; failures, 6 per cent.

Aseptic precautions were used in all the operations. The best vision obtained in any case was $\frac{20}{XV}$. Dr. Webster advocated the extraction of both lenses at the same sitting in judiciously selected cases.

Dr. Webster also related the history of a case in which he had relieved the pain in a glaucoma absolutum by lacerating the infratrochlear nerve—Badal's operation.

Dr. Henry D. Noyes, of New York, reported the

DEATH OF A PATIENT ON THE FIFTH DAY AFTER THE EXTRACTION OF A HARD CATARACT.

The operation, which was perfectly satisfactory, was performed on Sunday morning and the patient suddenly died the following Friday morning. After the operation a bandage was applied and the patient put to bed. The dressing was not disturbed until the third day. Everything seemed to be doing well, and the patient made no complaint. On Friday morning she suddenly complained of a feeling of prostration and within half an hour she died. The only lesions found at the autopsy were dilatation of the heart and insufficiency of the valves of the left side. The death seemed to have been due to heart failure. The contents of the orbit were removed *en masse*. A certain amount of force was used, and, as a consequence, the corneal wound was partially opened. The eyeball had been hardened and ten sections made to demonstrate the kind of union which we have at the end of the fifth day. Inspection of the eye before death showed that the union was smooth and apparently perfect. What is particularly interesting about these specimens is that the union appeared to have taken place exclusively through the medium of the epithelial layer.

Dr. David Webster, of New York, said that the more he had employed cocaine the more did he see the necessity of using as little as possible in cataract extraction. He attributed the bad results in some of his cases to the use of too much cocaine. In his later operations he has done about as Dr. Strawbridge has recommended.

Dr. B. Joy Jeffries, of Boston, had found it of decided advantage in cataract extractions to instil cocaine into both eyes. One drop a minute or two before the operation is sufficient. It renders the eye quiet, and the patient can keep it open.

Dr. C. R. Agnew, of New York, thought that the best plan to follow in the use of cocaine is to instil a drop of a four per cent. solution, and hold the lids open to allow it to become diffused; then wait three or four minutes; the eye may then be touched with an instrument to ascertain whether or not the sensitiveness has been sufficiently obtunded. One or two drops are usually sufficient, and employed in this way the possibilities of evil effects are reduced to a minimum. It had never been his custom to incarcerate patients in a dark room after a capital operation on the eyes.

Dr. W. F. Mittendorf, of New York, had seen two cases of serious complication after cataract, which he attributed to the use of cocaine. In one the eye was lost, and in the other it came near being lost. The cocaine solutions were fresh, but they were strong and used freely. He thought that one reason bad results are obtained is because the eye is left exposed to the air for several minutes after the introduction of the cocaine solution. Recent observations show that the injurious action of cocaine is especially upon the epithelial layer, and in shutting off the supply of lymph fluid. The epithelium suffers very rapidly from lack of moisture, especially if the eye is kept open. It has been recommended to close the eye immediately after the introduction of cocaine. He uses a weaker solution than a two per cent., making it fresh every day, by the addition of one or two grains of cocaine to half an ounce of water. Since using the weak solution and taking the precaution to close the eye after its instillation, he has had no serious accident.

Dr. Wm. Thomson, of Philadelphia, remarked that the first time he used cocaine he directed the apothecary to make a two per cent. solution; instead he made a solution of two grains to the ounce. Three operations were performed with perfect success, and it was not found out until afterward that a mistake had been made. Since then, he had not considered it necessary to use strong solutions.

Dr. Emil Gruening, of New York, said that last summer he went to de Wecker's clinic to see him perform cataract extraction without iridectomy. He learned that he employed this method only in the winter-time. The reason for this was that during the hot weather of summer the patients are very restless, and as a result prolapse of the iris frequently occurred. He decided to try the operation, and in May, 1886, performed his first operation. Half an hour before the operation he instilled a few drops of a solution of eserine (half a grain to the ounce). A few minutes before the operation the eye was cocainized with a four per cent. solution. There was no difficulty in removing the lens. After the operation eserine was again instilled, and the eye bandaged. Forty-eight hours later, the bandage was removed. The patient made pressure on the eyeball. The anterior chamber was emptied, and the iris prolapsed. He was compelled to remove the iris. There

were no further accidents. A few days later, he operated on a second case with perfect success. In regard to the action of cocaine, he referred to a case of an acute exacerbation in chronic glaucoma. The eye was very painful and very hard. He directed that a six per cent. solution of cocaine should be instilled. A few minutes later, on opening the lids and introducing the speculum, a bladder arose between its blades. Examination showed that this was the epithelium of the cornea, which had become raised. The operation of sclerotomy, which was about being performed, was postponed; but it eventually became necessary to remove the eyeball.

Dr. H. D. Noyes, of New York, had performed extraction without iridectomy in six cases. He had used cocaine. The cleansing of the anterior chamber and the removal of lens matter had been accomplished partly by manipulation and partly by irrigation. For washing out the conjunctival bag and removing matter from the anterior chamber, he uses a rubber bulb holding two or three ounces, and terminating in a short nozzle. It is not necessary to introduce a nozzle between the lips of the wound. The iris may be satisfactorily replaced by a stream of water. He used eserine, not as a preliminary, but as a dressing, in the form of an ointment containing two drachms of eserine to the drachm of vaseline. A small portion of this is placed in the conjunctival sac, and spread on a piece of linen covering the eye. In three of the six cases there was perfect union, with a central circular pupil and accurate vision. In one case intraocular hemorrhage came on twelve hours after operation, but this might happen under any method. In two cases prolapse of the iris was found on the seventh day, when the eye was carefully examined for the first time. The prolapsed iris was excised, and in one case the result was entirely satisfactory. In the second case no satisfactory vision was obtained.

His impression from this series of cases was that, while the operation deserves attention, the cases must be carefully selected. If the patient had but one eye, he would prefer to operate on it with a preceding iridectomy, and not without. He believes that a satisfactory result can be more certainly secured with iridectomy. As to the visual result, while theoretically it would be better, it is not always so.

Dr. Samuel Theobald, of Baltimore, in a case in which cocaine was used where there was stricture of the nasal ducts, has invariably observed that after the instillation of cocaine, the cornea, which has been clean and bright, becomes dull, presenting the appearance as though it had been roughly handled. He had noticed a similar result in another case.

Dr. B. E. Fryer, of Kansas City, said that in about ten cases he had used cocaine in this way: Inserting one drop every half hour until four or five drops have been used. In this way the iris becomes completely anæsthetized, and where we wish to perform iridectomy this is important.

Dr. B. Alexander Randall, of Philadelphia, remarked that there was one point not distinctly referred to in the discussion, and that was, whether or not inflammation of the iris is more frequent after this operation than where iridectomy is done. In the thirty or more cases which he saw at the clinic of Panas two years ago, there was not a single case of iritis. There were, however, several cases of prolapse. Panas claimed that there was less inflammation than after the ordinary operation. It is proper to say, with reference to iridectomy, that, with a small iridectomy, the pupil may be as movable and as central as in the operation described.

Dr. B. Joy Jeffries, of Boston, reported

SOME MEDICO-LEGAL CASES.

He first read the law of Massachusetts in regard to the examination of railroad employees and others for color-blindness, and stated that it was practically a dead letter, and could not be enforced. In order to make it efficient, some standard test must be adopted. Many instances in which the law had been evaded or ignored were given. Many cases were cited, particularly of railroad engineers and steamboat pilots, where lives of many passengers had been endangered by this defect.

Dr. Charles A. Oliver, of Philadelphia, exhibited and read a description of

A NEW SERIES OF LOOSE WOOLS FOR THE SCIENTIFIC DETECTION OF SUBNORMAL COLOR-PERCEPTION (COLOR-BLINDNESS).

They comprise ninety-seven bundles of Berlin worsteds, composed of five large principal test-skeins, twenty small pure match skeins, and seventy-two small confusion skeins. To each small skein there is attached a metallic bangle, bearing the exact equivalence of the color's composition, tint, and shade, stamped upon it in a way that can only be understood by the surgeon. The colors are all of equal relative intensity; the wools are all of one manufacture, and have been dyed with vegetable materials.

The following advantages are claimed for the series: That there are five tests; that the wools are loose, and all of the colors of the same relative intensity; that each skein has its value expressed, so that the skeins can be employed by any intelligent layman; that accurate notings of color changes can be made for future comparison, and proper verbal and written expression can be given; that by reason of the wools all being of the same grade of manufacture, and all the colorings obtained from vegetable dyes, no results can be gotten from the supplemental sense of touch; and, finally, that a black surface is employed, and no definite order of testing need be pursued.

Dr. Wm. S. Dennett, of New York, exhibited a set of Holmgren's worsteds which had been made into spheres, and to each one a number was attached. It was thought that considerable elegance and some advantage would result from using Holmgren's or Thomson's test in this manner.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, May 24, 1886.

The President, James T. Whittaker, M.D., in the Chair.

(Continued from page 109.)

THE MEDICAL TREATMENT OF ECHINOCOCCUS.

Dr. A. B. Thrasher remarked that there is unanimity of opinion among authors with reference to the therapeutic treatment of echinococcus, namely, that it is unsuccessful. The case reported by Leidy was referred to in evidence of the futility of medicinal treatment. In

that case, after the subject had been injected with a strong solution of the chloride of zinc, and after all the tissues had become thoroughly blanched, there was still evidence of living hydatids. The hygienic care of the patient is of importance, and the subject of prophylactic measures opens a fruitful field of study.

Dr. R. B. Davy agreed with the last speaker that very much cannot be said in praise of the treatment of echinococcus with the administration of medicines by the mouth, some authorities to the contrary notwithstanding. When the echinococcus disease has been diagnosticated beyond a peradventure, it is customary to prescribe something to be taken by the mouth, whether or not it becomes necessary to pursue other treatment. In the event of the death of the endocyst during the continuation of said treatment, and such a thing may occur from purely accidental causes, the drug used gets the credit for the cure. In this way, Hjaltelin claims to have cured twenty-two persons with the tincture of kamella; Heckford caused the disease affecting the liver to disappear in five weeks with twenty-seven grains daily of the iodide of potassium, and Reeb, with the same remedy, thought he had several times cured echinococcus of the brain. The salts of mercury, turpentine, etc., have been spoken of as possessing similar power over this parasite, but most authorities doubt the curative effect of any drug administered by the mouth. Of the forty-six cases reported by Heller as occurring in English hospitals, thirty-six were cured by puncture alone with the escape of part of the fluid. In the remaining ten suppuration occurred, making a larger opening necessary, and two of these cases died. The fact that so many of these cases should terminate favorably after the escape of often a small amount of fluid, is very significant. The condition is not at all unlike that which might be brought about by the action of a hydragogue cathartic, active diuretic, or diaphoretic. By agents of this kind the blood stream is robbed of its water, and the cyst is in turn deprived of some of its fluid through the absorbents. The tension of the fluid within the cyst being thus reduced, the parasite might be made to die without further interference. I have no desire to be understood as seconding the treatment of echinococcus by the administration of drugs, except in cases where the aspirator needle, the surgeon's knife, etc., are not applicable, yet I cannot help believing that the benefits attributed to them are brought about in the manner described, and not by any special deadly influence over the parasite. Cobbold, in discussing the effect of drugs administered by the mouth, describes the dense ectocyst and the difficulty or impossibility of reaching the vital endocyst with blood sufficiently charged with any anthelmintic to produce any effect upon it. Hearn says that the medical treatment of hydatids in no way affects the prognosis; and Todd affirms that the only cure for them is their evacuation. Notwithstanding these dogmatic assertions, it must be accepted that trivial influences often affect the vitality of the parasite, and that its death sometimes takes place without any assignable cause. It is, therefore, well to bear in mind that medicines internally, as well as electrolysis, aspiration, and the injection of certain drugs directly into the sac are not to be lost sight of in our hurry to plunge in the bistoury and terminate the case. While prompt treatment is important in rapidly growing cases, slow ones should be handled with moderation and caution, for it is often better to resign the parasite to natural decay than to subject the patient to unnecessary risk. In the hands of Fagge and Forster, electrolysis seems to have been used with advantage, while with other observers the injection of iodine, carbolic acid, gall, etc. has found favor. In ruptured and discharging hydatids of the lung, where the breath is liable to become very offensive, an efficient deodorizer is called for. Heller advises inhalations of turpentine to overcome this difficulty, but it is hardly apparent that this agent should be superior to zinc chloride, carbolic acid, iodine, etc.

In hydatid of the brain or heart, where it is possible to arrive at a diagnosis, the slender hope attached to the use of medicines by the mouth is about all that is left and should not be minimized. In these cases a lesson might be learned from the rest and starvation treatment of aortic aneurism. So much then for the medical treatment of echinococcus. As may be seen, it is not entirely devoid of importance, yet stands much beneath the possible aid of the surgeon. The importance of every kind of treatment stands eclipsed by prevention.

The prophylaxis of echinococcus is to the treatment of the disease, Dr. Davy continued, as life is to death—the one filled with smiling possibilities, the other loaded with gloomy forebodings and disappointments. By proper attention to this subject many observers think that the disease may be actually stamped out. In Iceland, where one-sixth of all deaths are from this cause, Krabbe affirms that twenty-eight per cent. of the dogs are infested. These dogs often come into the closest contact with their masters. The dog's intestines are the acknowledged home of the tænia echinococcus, and in passing with the feces ova may adhere to the anus, to be in turn transferred to the dog's nose and mouth. After this, food or drink shared with the dog is a possible source of infection. This intimate association between dog and master could hardly be possible in our country, yet the equally dangerous habit of kissing the pug or lap-dog is common enough. To avoid these dangers of infection, Leukhart advises that all dogs be kept aloof from slaughter houses and that suspicious offal be burned. Leared says that dogs should be purged at intervals with anthelmintics and cathartics, and Cobbold advances the idea of disinfecting their feces with boiling water. Still-water to which dogs have access should not be used for drinking, as even in this country it can never be regarded as safe. Meat inspectors of cities and towns should thoroughly understand the habits and haunts of these parasities—as they do not—and be able to act intelligently in the effort toward exterminating them. The eating of uncooked meats should for this and other reasons be carefully avoided.

NEWS ITEMS.

MONTREAL.

(*From our Special Correspondent.*)

New Health Bill.—The new Health Bill which was passed before the dissolution of the Legislature, is a very weak affair. Neither political party wished to pass

a very stringent bill, as the Provincial elections are close at hand. The *habitants* strongly object to compulsory vaccination, and the ecclesiastical authorities to compulsory registration of births. So both these most important clauses of the bill were dropped, and the consequence is that we now have an emasculated health bill which can be of but little service to the country.

Laval and Victoria.—The dispute between these two medical schools is not yet settled, and appeals are still being made to Rome to decide in favor of one or other school.

Within the last month several professors of the rival schools have sailed for Europe, and it is believed by many that their destination is Rome, and their object to plead the cause of the schools they represent before the Pope, who, apparently, is the director of even medical education in French Canada.

Hydrophobia.—Dr. Rodier, who has been sent over to France by the Provincial Government of Quebec to learn Pasteur's methods of inoculation for rabies, has arrived in Paris, and has been well received by the great scientist. It will seem strange to outsiders that whilst other countries are sending their ablest and most experienced men to investigate and report on Pasteur's methods, the Province of Quebec should be satisfied to be represented by a young man who has but just graduated (1886), who could have had no experience, and who, so far, has shown no special aptitude for scientific research; but here, as well as elsewhere, politics is at the bottom of the evil.

Whilst on this subject it might be mentioned that no case of hydrophobia has occurred here within the memory of man, the disease being unknown. One of the Governors of Canada is said to have died of rabies many years ago, due to the bite of a pet fox; but with this exception no other case is known. Some deny that this was a case of rabies.

Canada Medical Association.—The annual meeting takes place in the city of Quebec on the 18th and 19th of August, under the presidency of Dr. Holmes. A large number of papers have already been promised, and a very successful meeting is expected. A number of prominent men from your side of the line have promised to be present.

College of Physicians and Surgeons of the Province of Quebec.—The triennial meeting of the College was held here on the 14th instant.

The amendments to a medical act submitted by a committee of the Council were submitted and approved. The amendments provide for a compulsory examination in all subjects before a board of examiners, English and French, appointed by the medical schools and Council. No medical degree will entitle the possessor to take out a license as heretofore, but all persons, without exception, will have to pass an examination in both primary and final branches not less than four years after having passed the preliminary examination in classics, mathematics, literature, and philosophy.

Heretofore holders of Canadian or British diplomas were entitled to registration as qualified practitioners, provided they had studied four years after passing a prescribed preliminary examination. The amendments also provide that the Province of Quebec shall be divided into six electoral districts, each district to elect its own representatives to the Council.

The following office-bearers were elected for the new Council:

President.—W. H. Hingston, M.D.

Vice-Presidents.—Hon. Dr. Ross and J. L. Leprohon.

Secretaries.—F. W. Campbell, M.D., for Montreal; A. G. Belleau, M.D., for Quebec.

Treasurer.—E. P. Lachapelle, M.D.

Registrar.—L. La Rue, M.D.

In consequence of a provision in the new Medical Act in Great Britain, holders of British qualifications will not be entitled to practise without examination in the Provinces of Ontario or Quebec.

Stale Eggs.—At a recent meeting of the Council of Hygiene, in the Department of the Seine, France, a question was raised as to the fitness for food of eggs which had been laid for a considerable length of time, and which offered certain peculiarities, such as external and internal spots, and the yolks having a strange color, and adhering to the shell. Various considerations on the subject had been submitted to M. Chatin, with the request that he would inform the Council whether, in the case of eggs so affected, it would be necessary to prohibit their sale. The reporter stated that eggs which had spots about them were not necessarily damaged, and that they might be used by bakers and confectioners for glazing bread, and some kinds of pastry, whilst the whites could be used by leather-dressers, who employ albumen in the preparation of articles made of leather. He added that eggs which were really damaged could easily be distinguished on account of the smell. Under these considerations, M. Chatin thought there was no necessity to forbid the sale of them. That a stale egg may, in some cases, be safely eaten, like high game, is quite comprehensible; but game, as well as eggs, cannot be eaten when putrid beyond a certain extent, probably because germs of extreme septic virulence, resisting the gastric juice, have been developed. In the earlier stages of decomposition, both these articles of diet appear to remain innocuous, the game being toothsome to the many, the eggs to the few.

Accouchement of a Turkish Princess.—Dr. J. A. S. Grant was called upon to attend a Turkish Princess in confinement, she having heard that he would administer chloroform. Everything connected with the delivery passed off successfully and it is considered a most auspicious introduction of chloroform and medical men into the harems for confinements.

The Strength of Spirit of Nitrous Ether.—A question of some importance to the medical profession came the other day before the Thames Police Court, when Mr. John Read Morrison, a practitioner, of 57 Cannon Street, St. George's-in-the-East, who keeps a shop, was summoned for selling a quantity of spirit of nitrous ether not of the nature and quality of the article demanded, the drug being deficient in nitrous ether to the extent of eighty per cent. Mr. William Raines, sanitary inspector to the parish of St. George's-in-the-East, said that on June 10th, about 11 o'clock, he called at the

shop and asked for two ounces of spirit of nitrous ether, which the defendant served him with, and for which he paid 8*d*. Witness then told him that it would be analyzed by the public analyst. The analyst's certificate showed that the drug was deficient in nitrous ether to the extent of eighty per cent. Mr. Young, who defended, submitted that there had been no offence. The article was pure, and the deficiency was caused by decomposition and evaporation. Mr. John Beckett, assistant to Dr. Tidy, at the London Hospital, said he had analyzed the sample of the drug submitted to him by the defendant, and found it to be pure. The nitrous ether was liable to decomposition and evaporation. There was certainly a deficiency. Every time the bottle was opened, some of the nitrous ether would go out. Mr. Hannay said it was too important a question for him to decide at once, and he adjourned the case for a week.

FEMALE PHYSICIANS IN THE FIFTEENTH CENTURY.—Dr. Horowitz, of Frankfort-on-the-Main, has (*The Jewish Chronicle*, May 14, 1884) published a work, entitled "Jüdische Aerzte in Frankfürt," in which the learned author mentions the interesting fact that, as long as four hundred and fifty years ago, Jewesses practised medicine in that city; they especially devoted themselves to ophthalmia. The female oculist, Dr. Zerlin, whom we meet with in the volume as having practised in the year 1428, ventured to reside outside the Judengasse, and believed that she could claim exemption from the payment of taxes on account of her talent, and the general esteem in which she was held. The municipal council rejected her application, and, in 1489, they ordered that Jewish lady doctors should either quit the city or pay taxes like other Jews. A Jewish doctoress was, however, more fortunate in the year 1494; she was relieved from the payment of "sleeping money," a tax imposed on foreign Jews for every day that they stayed in Frankfort. With this exemption was coupled an official recognition of her profession, which was of the utmost advantage to the lady.

MEDICAL MALPRACTICE IN CHINA.—The Chinese penal code does not favor medical malpractice, as the following quotation will show. "Whenever an unskilful physician, in administering medicines or using the acupuncture needle, proceeds contrary to the established forms, and thereby causes the death of the patient, the magistrate shall call in other physicians to examine the medicines or the wound. If it appear that the injury done was unintentional, the practitioner shall then be treated according to the statute for accidental homicides, and shall not be allowed any longer to practise medicine. But if he have designedly departed from the established forms and have practised deceit in his attempts to cure the malady, in order to gain property, then, according to its amount, he shall be treated as a thief; and if death shall ensue from his malpractice, then for having used medicine with intent to kill he shall be beheaded."

DR. THOMAS R. FRENCH, of Brooklyn, has been appointed to the Chair of Laryngology in the Long Island College Hospital.

DR. CUTTER'S DICTIONARY.—A German-Japanese medical dictionary has just been published in Tokio. It was compiled by Dr. Shigu, a government examiner in medicine, and Messrs. Take and Shibatta, officers of the Sanitary Bureau. The work contains 1400 German terms, with definitions in Japanese, and it is stated in the preface that it is based upon the "Dictionary of German Terms used in Medicine" compiled by Dr. George R. Cutter, of New York.

DR. JOHN C. DALTON received the degree of LL.D. from Princeton College at its last commencement.

A POST-GRADUATE SCHOOL is to be organized in Edinburgh, and another, possibly, in Glasgow.

OBITUARY RECORD.—CHARLES W. FABYAN, M.D., died July 23d, at Providence, R. I., where he had practised medicine since 1840. Dr. Fabyan was in his seventy-fourth year. He was born at Scarborough, Me., and graduated from the Bowdoin Medical School in 1837. He was a Fellow of the Rhode Island Medical Society, and was highly esteemed as a citizen and a physician.

NOTES AND QUERIES.

LIME-WATER AS A DETERGENT.

To the Editor of THE MEDICAL NEWS,

SIR: In my practice I am obliged to make frequent utero-vaginal examinations and applications, and in cleaning the parts of catarrhal or leucorrhœal discharges, especially those of a more tenacious character from the cervix uteri, I have found the operation greatly facilitated by the application of lime-water, either by syringe or on cotton. Respectfully yours,

M. G. LEWIS, M.D.

HAYWARD, WIS., June 30, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JULY 24, 1886.

CARMICHAEL, D. A., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, July 24, 1886.

MAGRUDER, G. M., *Assistant Surgeon.*—To proceed to Cairo, Ill., for temporary duty, July 22, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM JULY 20 TO JULY 26, 1886.

PERIN, GLOVER, *Colonel and Assistant Surgeon-General.*—Leave of absence extended one month.—*S. O. 165. A. G. O.*, July 19, 1886.

GIBSON, J. R., *Major and Surgeon.*—Ordered from Department of the East to Department of Missouri, on expiration of leave of absence granted in S. O. 158 c. s., A. G. O.—*S. O. 168, A. G. O.*, July 22, 1886.

GARDNER, WM. H., *Major and Surgeon.*—Granted four months' leave, to take effect August 10, or as soon thereafter as his services can be spared.—*S. O. 165, A. G. O.*, July 19, 1886.

MIDDLETON, PASSMORE, *Major and Surgeon.*—Ordered to Department of the East from Department of Missouri.—*S. O. 168, A. G. O.*, July 22, 1886.

DE WITT, CALVIN, *Major and Surgeon.*—Assigned to duty at Fort Sully, Dakota.—*S. O. 66, Department of Dakota*, July 14, 1886.

DICKSON, JOHN M., *Captain and Assistant Surgeon.*—Ordered from Alcatraz Island, Cal., to Fort Mason, Cal.—*S. O. 56, Department of California*, July 8, 1886.

COCHRAN, JOHN J., *Captain and Assistant Surgeon.*—Ordered from Fort Mason, Cal., to Presidio of San Francisco.—*S. O. 56, Department of California*, July 8, 1886.

GIBSON, A. J., *Captain and Assistant Surgeon.*—Ordered from Fort Winfield Scott, Cal., to Alcatraz Island, Cal., on return from leave of absence.—*S. O. 56, Department of California*, July 8, 1886.

ORIGINAL ARTICLES.

INTESTINAL CASTS: WITH THE REPORT OF A CASE.

BY WILLIAM A. EDWARDS, M.D.,

INSTRUCTOR IN CLINICAL MEDICINE AND PHYSICIAN TO THE MEDICAL DISPENSARY IN THE UNIVERSITY OF PENNSYLVANIA, PHYSICIAN TO ST. JOSEPH'S HOSPITAL, ETC.

A DISEASE upon which a century of American medicine has brought forward but a dozen writers, is of sufficient rarity and interest to claim our careful study and investigation. Until Da Costa published his article on membranous enteritis in the *American Journal of the Medical Sciences*, in 1871, American physicians, with but one or two exceptions, did not seem to have recognized the disease as a separate and distinct ailment.

The earlier cases occurred in England and on the Continent, but in the last decade the cases seem to be about evenly distributed between England and America; about this time a disease similar to the one under consideration was described in the lower animals by Th. Clemens and Engesser, who relate cases occurring in cattle, the membranes in one of the cases[1] measuring fifteen feet in length.

An unfortunate chaos in the nomenclature undoubtedly has done much to retard the study, classification, and correct interpretation of this somewhat rare disease. Almost every writer on the subject has advanced a name different from any title given to the before recorded cases, for example: Tubular looseness or diarrhœa tubularis;[2] chronic pseudo-membranous gastro-enteritis;[3] follicular, duodenal, and clonic dyspepsia;[4] fibrinous diarrhœa;[5] chronic pellicular inflammation of the intestinal mucous membrane;[6] chronic croup of the intestines;[7] mucous disease of the colon;[8] chronic muco-colitis;[9] mucous disease[10] and membranous enteritis;[11] painful affection of the intestinal canal;[12] pseudo-membranous enteritis;[1] intestinal desquamative catarrh;[2] a membrane-like affection of the bowels;[3] intestinal cast.[4]

I feel that Good, in styling the disease tubular diarrhœa, is more nearly correct, as by so doing he advances no theory which would endeavor to explain the condition. By using the title which heads this article we simply express the condition as we find it—*i. e.*, an intestinal cast—not endeavoring by our nomenclature to cover the pathogeny and etiology of the affection as so many writers have unsuccessfully attempted. Perhaps in no way can a better understanding be had of the disease than by recording our case.

Susan H., aged thirty, light mulatto woman of good physique, weight one hundred and fifty pounds, married nine years ago, had one child, born last May (1884), made a good recovery. No miscarriages or history of uterine complaint. Has always enjoyed good health, is neither nervous nor hysterical, and gives no history of a hereditary taint of any kind. November, 1884, she suffered from a severe attack of dyspepsia, after which first passed an intestinal cast which was quite *fourteen* inches in length, and dark in color,[5] it was thought to be a worm, and patient was treated accordingly; since November has frequently passed casts, suffers no pain during or preceding passage, says that in last six months has passed a "bucketful" of them. No colic, tumefaction, or diarrhœa—in fact, bowels must be kept regular by the use of medicines. Blood never occurs in the discharges. Feels a sensation of "something moving" before cast is expelled; the passage of the casts has been almost constant for the last six months, not occurring in paroxysms. Patient says that she feels well, and were it not for the anxiety that her condition causes her, would consider herself in perfect health.

The disease is generally seen in hysterical women, or hypochondriacal men who have suffered from dyspepsia and its concomitants. A few cases have been reported as occurring among children.[6]

Most reporters say that the disease is characterized by attacks of abdominal pain, followed by discharges of the casts; our case suffered neither before nor after the discharge, although, as above stated, some of the casts were fourteen inches in length. Regarding the frequency of the discharges, there may be but a

single discharge or they may be almost continuous, as the case we are considering well illustrates. A fact worth noting is the almost entire lack of emaciation notwithstanding the quantity of matter passed. During the intervals of the attack, diarrhœa may be present or the bowels may be constipated; tenesmus is frequently a symptom complained of bitterly by the patient.

Subjects of this disease, while not emaciated, will generally present evidences of malnutrition, as shown by furuncles, carbuncles, sore mouth, and irritable nervous system. The bladder may or may not present symptoms; it generally does, however, in females.

Da Costa (*loc. cit.*) records a case in which the patient could predict an attack with certainty; the premonitory symptoms were blueness of nails, tingling or pain at tips of fingers, and a sense of chilliness.

Hess[1] had under his care a married woman aged thirty-two, who had had two miscarriages and one child at full term; dyspepsia and constipation, alternating with diarrhœa, had existed several years before the patient came under observation. She passed pieces a foot long; every passage for five or six weeks contained these casts. She never passed any blood. Appeared to know when the pieces became loose, as she could feel them moving their entire course through the intestinal canal.

Fish[2] noted the case of a woman aged forty, in whom constipation and uterine disorder preceded the expulsion of the membranes. No blood was noted at any time; patient passed membranes about twice a week

In the cases recorded by F. W. Goss,[3] habitual constipation was a marked symptom; one patient had exacerbations of the disease lasting one, two, and three months, passed a substance that looked like a tangle of "white wet string." In another case a similar discharge from the vagina accompanied that from the bowels. The membranes have been noted a quarter of a yard in length. In his third case some of the membranes had a dark colored central fibre running through them, that was as difficult to sever as a wire. All the cases were females, and about or above middle age.

Whitehead[4] remarks that, out of one hundred cases, *only four* occurred in males; on the whole, females seems to offer a predisposing diathesis; at all events, cases are more frequent among women.

In the *New York Medical Record* (1882, ii. 33–36), we find the case of Mrs. N. recorded, which presents a point of some interest in the fact that she suffered great pain during the attack; the seat of the greatest pain was a spot a little above the umbilicus; the discharges in this case were very offensive.

That physicians and patients may occasionally be mistaken in this disease, witness the following cases. Quekett (Rich. Quain, Ibid.) describes the case of a woman who at intervals of a fortnight or three weeks, had paroxysms of abdominal pain, which were relieved on passing a quantity of membranous matter and tubes, the mass of which sometimes exceeded an orange in size. This mass represented the undigested portion of mutton chops, which had constituted the meat diet of the patient. He states that he has observed *nine* cases of this character.

Corrigan[1] found the substance passed to consist of yellow elastic tissue, resembling the ligamentum nuchæ of sheep. Cases are sometimes met in which hemorrhage becomes a prominent or alarming symptom.

Van Valzah[2] noted a case in which the matter passed was not unlike "boiled macaroni." "There is a long history of nervous disorder, a peculiar skin disease, derangement of the sense of sight, irregular uterine function, dyspepsia, high-colored urine, intestinal disorder terminating in distinct attacks of pain accompanied by characteristic discharges from the bowels;" the pain now comes on at regular intervals, relieved with the appearance of the discharge. There was also increased mental activity, and a severe hemorrhage (melæna), the amount of matter discharged was marked and persistent.

I cannot better describe the macroscopic and microscopic appearance of these casts than by quoting from the admirable article of Goodhart.[3]

> Material consists of: 1st, an elongated network of roundish cords; 2d, white, opaque, solid masses of some inches in length, with small secondary folds on their surfaces, all of which are arranged parallel to the long axis of the mass; 3d, small flocculent pieces of semi-translucent membrane, which, even by naked eye, may be seen to have a corrugated or reticulated arrangement.
>
> The more solid fibres, at their free ends, and on the unattached edges of the secondary folds, oftentimes merge gradually into a perfectly clear and colorless jelly which is hardly visible when placed in water. The cone-like networks have the most consistence, but all three varieties are so delicate as to allow of but very little manipulation out of water.
>
> Microscope: Under two-inch objective, surface is seen to be composed of opaque and translucent parts, the former apparently as round ridges, marking off the latter into regularly arranged hexagonal or polygonal crypts. Under a higher power these crypts are still visible, though much less well defined. These appearances are best seen in the small flakes of membrane, less distinctly in the larger masses, but not in the networks. They appear to be due to the formation of mucus and epithelial matter, either upon the surface of or in contact with some follicular mucous membrane.
>
> The mouths of the follicles on the surface of the cast, when compared with the mucous membrane from a healthy piece of large intestine, present the following differences. They are much larger in the proportion of two or three to one, while the intervening tissue forming their wall is much less. There is also much less structural arrangement in the cells forming the walls in the membrane passed, and while in the healthy gut distinct basement membrane exists, no such membrane can be seen in the casts.
>
> Under the least pressure all the specimens break up immediately into isolated collections of cells, these being of various shapes and sizes; but the greater number

are elongated and blunt at one end, having the appearance of disintegrating columnar epithelium. On making a section vertical to the surface, and being careful to make no pressure with the cover-glass upon the specimen, indistinct pieces of tubes or their moulds may here and there be seen, but only once or twice were these very distinct. All stain deeply with carmine, in inverse proportion to their opacity, gelatinous parts staining most deeply. Chemically, all are dissolved by alkaline solutions, by strong hydrochloric acid and heat.

It becomes interesting to inquire into the pathology of the affection, but at the outset we are met by an extremely meagre literature, but few post-mortems of the disease having been recorded. Simpson mentions a case, seen by Abercrombie, in which the mucous membrane of the colon was covered by an immense number of small spots of a clear white color, which were vesicles that, when punctured, discharged a small quantity of clear fluid. This patient had suffered from phthisis, and had passed a large quantity of "membranous casts or tubes."

Da Costa is of the opinion that the affection is not originally an inflammation, but considers the inflammatory element as the result rather than as the cause, and would attribute the true etiology to the nerves presiding over nutrition. In Wright's case the mucous membrane of the colon and lower portion of the small intestine was studded with a thickly set papular eruption.

The colon seems to be the seat which the disease elects; this, however, is not the invariable rule. The middle period of life also seems to be the age at which the passage of intestinal casts most frequently occurs. Again, however, this is not without exceptions; as has been stated, a few cases have been met with in children.

The existence of diarrhœa tubularis may always be determined if ordinary care is taken; it may be mistaken for dysentery and fatty discharges; again, it has been mistaken for worms. In diphtheria the intestines may be attacked by diphtheritic membrane, and the casts passed per rectum. An extremely interesting case showing how diphtheria may present casts of a portion of the alimentary tract, is recorded in a late number of the *Amer. Journ. of Med. Sciences*.

In pyæmia, scarlet fever, puerperal fever, and tubercular disease, a membrane is sometimes deposited and cast off. These are cases of "secondary croup of the intestinal membrane."[1] The prognosis is not good; many cases, however, run a prolonged course, as in the patient of Broca,[2] whose disease lasted fifteen years. Very acute cases occasionally make a complete recovery; this unfortunately is a rare exception instead of the invariable rule. The treatment, as one would suppose, is extremely unsatisfactory. It is well, however, to endeavor to ward off attacks, to prevent the reformation of membrane, and to treat symptomatically during the persistence of an attack. During the acuteness of a paroxysm, opium is perhaps the drug that will best meet the indications. Belladonna, Dover's powder, bismuth, and counter-irritation all have their advocates.

During the remissions a suitable diet is the most important part of the treatment. The patient must take plenty of outdoor exercise, and the skin is to be kept active by baths and massage. Abdominal counter-irritation is to be persisted in for a long time over the course of the colon, as in many cases we find tenderness in this region.

Fowler's solution is, in some cases, a very happy remedy. Strychnia may also be exhibited. Habershon recommends nitro-muriatic acid, henbane, and vegetable infusions; Clark,[1] nux vomica and copaiba; and Whitehead, the bromide of potassium; Cumming[2] advises the use of the battery in quarter-hour daily *séances*.

The following drugs have also been used with more or less transient success: Turpentine, iron, cod-liver oil, oxide and nitrate of silver, muriate of ammonia, sulphate of zinc, tar water, chlorate of potash, corrosive chloride of mercury, blue pill.

Purgatives are distinctly contraindicated; when the bowels become sluggish and constipated, as they are apt to do, only mild laxatives should be administered.

ACUTE OPTIC NEURITIS OF RHEUMATIC ORIGIN.

TWO CASES—ONE MONOCULAR.

By H. F. HANSELL, A.M., M.D.,

Adjunct professor of diseases of the eye in the Philadelphia polyclinic.

Acute and chronic inflammation of the optic nerve is one of the most frequent intraocular affections met with in ophthalmic practice. It is, however, by no means confined to the practice of the ophthalmic surgeon, as an enumeration of its causes, and the diseases of which it is a complication or a symptom will indicate. West (*Trans. Ophth. Soc. of Great Britain*, 1882–83) reports twenty-two cases due to injuries of the head and intracranial diseases; Burnett and Oliver (*Amer. Journ. Med. Sci.*, 1884), a case of monocular optic neuritis in which, while the neuritis was subsiding into atrophy, general ataxic symptoms were manifest; Sharkey (*Oph. Soc. Great Britain*, 1884), a case of acute optic neuritis with absolute blindness in four days followed in six weeks by paraplegia with anæsthesia, incontinence of urine and feces, cystitis, peritonitis, and death; Eulenberg (*Neurol. Centralb.*, No. 15, 1884), a similar speedily fatal case. Gower (*Med. Ophthal.*, 2d ed.) describes optic neuritis as occurring in chronic cerebritis, cerebral hemorrhages, softening, abscess, tumors, inflammations and tumors of meninges, rarely in cerebro-spinal meningitis, diseases of the cranial bones and orbit, injuries to the head, myelitis, renal inflammation, leucocythemia, acute and chronic menstrual irregularities, "common in syphilis as a secondary disease, but is very rare as a primary syphilitic affection, if it ever occurs." In speaking of rheumatic influences he says, "Neuroretinitis has been loosely ascribed to rheumatism, but only on the ground that it has sometimes appeared to be due to cold. It must be remembered that the optic nerve, like the other orbital nerves, may be damaged by rheumatic inflammation at the back of the orbit." As other causes he cites lead and other intoxicants, typhus, typhoid, scarlet fever, measles, variola, erysipelas, and diphtheria.

In an inaugural dissertation (Berlin, 1885) Max Haadel reports nine cases of acute optic neuritis, some monocular, occurring under such circumstances that exposure to a draught of air was the most frequent cause. Absence of albuminuria, diabetes, syphilis, lead, and other forms of intoxication, was shown in every case. Leber (Gräfe and Saemisch, *Handbuch*, S. 814) relates the case of a gunner who, in three days after prolonged exposure from standing in deep cold water, was entirely blind from optic neuritis; also of a country postman, exposed by the nature of his calling to all weathers, who suffered from rheumatic monocular optic neuritis. Arlt (*Augenkrankheiten*, Bd. iii. S. 159) speaks of a man who, after hard dancing, exposed his perspiring body to a draught, suffered gradual loss of vision, followed in four years by central symptoms; he quotes Holscher, who records the case of a healthy woman, twenty-two years old, who took a severe cold, rapidly became blind, and died in seven days; Makenzie, the case of a young woman who, while perspiring freely, thrust her hands into cold water—she had a chill, skin became dry in a moment, and in fifteen minutes she was blind; and another of blindness supervening in twelve hours after exposure.

Two cases are reported by Beer (*Lehre der Augenkrankheiten*, Wien, 1792, B. ii. S. 51), and quoted by others, in which the exposure was the indirect and suppression of menses the direct cause of the neuritis: a girl, eighteen years old, one morning in winter, during her sickness, walked with bare feet on the marble floor of the kitchen. In ten minutes she could not discern the brightest light. After the menses were restored, the vision was entirely recovered. In the other case vision was lost during six months from the same cause, and returned after the menses were reëstablished.

Some allowance must be made for the cases which were reported prior to the days of the ophthalmoscope. The above, however, are all plainly instances of amaurosis from acute inflammation of the optic nerve.

Case I. *Monocular.*—Mrs. A., a strong, healthy-looking woman, consulted me on June 8, 1885, on account of defective vision and pain. She had worn R. and L. —4 for eight years, for distance only, with moderate comfort. Three weeks ago she began to complain of a constant, deep-seated pain in the eyeballs, and of occipital headache. Ophthalmoscope showed myopia —3, and vertically oblong disks. *Fundus healthy.* R. V. $\frac{10}{cc}$; L. V. $\frac{15}{cc}$.

Thinking her pain and headache caused by wearing an improper corrective, I ordered a laxative pill, and dubois. sulph., gr. j–℈j, to be instilled into the eyes to paralyze the accommodation. The patient was to return next day for measurement of refraction. The following week she was kept at home by a very sore foot—a corn which had become inflamed, resulting in an abscess. On June 18th she complained that two days before the sight of the right eye had become very dim. I found vision reduced to counting fingers at three feet; pupil dilated and immovable (duboisia?); media clear, optic nerve moderately swollen, outlines of disk lost, arteries normal, veins tortuous, no hemorrhages. Field not limited. Left eye normal and remained unaltered. She was ordered to bed in dark room; copious local bloodletting. Hydrarg. chlor. mit., gr. $\frac{1}{12}$, until salivation. The vision sank until all light perception vanished, and remained so for forty-eight hours, then commenced to return, and in seven days was entirely restored.

R.—2.50 = $\frac{20}{XX}$. L.—2.75 = $\frac{20}{XX}$.

On closely questioning the patient, and being able to exclude all known diseases and poisons, only two possible causes could be discovered. On a very hot night, between her first and second visits, she had lain, thinly clad, on the floor of her bed-chamber;

and upon rising felt that she had taken cold. The other and less likely cause may be found in the suppurating corn. Just what connection exists between the corn and the optic nerve of the other side is hard to define, yet the relation of cause and effect is not impossible. Arlt (*op. cit.*) assigns the application of leaves of rumex to the feet to stop sweating in an old man as the cause of his neuritis; and Beer relates a case of absolute blindness caused by suppression of a purulent discharge from ulcers on the feet, cured by reëstablishing discharge by means of mustard plasters.

Case II. *Double.*—A healthy man, aged thirty-one, occupation switchman on a railroad, consulted me December 2, 1885. For past ten days had severe frontal headache, followed, during last three days by rapid loss of vision; otherwise perfectly well, and no history of syphilis. R. V. counting fingers at one foot; L. counting fingers at two feet. R. field limited on nasal side; L. not limited. Both disks swollen. R. = 3 D.; L. somewhat less; no hemorrhages; pupils dilated but responsive. Ordered home to bed; blisters on each temple; hydrarg. chlor. mit., gr. $\frac{1}{12}$ every hour. In two days all light perception was lost, except at extreme temporal side of R. field; pupils widely dilated and immovable. L. nerve swollen equal to right. For four days this condition remained unchanged. The patient was now completely under the influence of mercury without the slightest improvement. He was next bled freely from the arm, and *while the blood was flowing from the vein the perception of light and large objects returned.* Profuse sweating, by infusion of jaborandi, further improved the vision. The next two weeks he took potas. iod., gr. xv, hydrarg. chlor. corros., gr. $\frac{1}{18}$, four times daily.

Jan. 6.—V. = $\frac{20}{L}$. Patient then disappeared, but it may be presumed vision became fully restored.[1] On the day of last examination both backgrounds were normal. The swelling had subsided, exudation absorbed, and disks regained their healthy color. On the first examination the vision was so bad that nothing decided could be learned of the color perception or condition of accommodation. No albumen and no sugar in urine. The cause in this case was probably exposure.

The pathology is decidedly obscure. Arlt, in the autopsy of a case which died of paralysis four years after the optic neuritis, found the envelopes of the brain greatly congested and tense, and, when opened, "emptied eleven and one-half cupfuls of brownish-red dirty water from the side ventricles." In another, in which there were no other than ocular symptoms and death on seventh day, twelve to fourteen ounces of clear serum distended the ventricles. In Edwards and Lawford's twenty-two cases of neuritis complicated with injury and diseases of the brain in which the optic nerves were examined, the conclusion was reached that the inflammation of the meninges had extended to the sheaths of the optic nerves and thence into the nervous tissue through the fibrous network. The pathology most commonly accepted is a dropsy of the nerve sheaths. If Arlt had included the optic nerve in his examination, he would most probably have found the outer covering (dura mater) of the nerve widely distended with serum and the pia mater (neurilemma) and optic nerve compressed. Leber says, "The association of a high grade of this change (hydrops) with the above described brain affection (hydrocephalus internus) is an established fact. In all cases the hydrops was double-sided, but not equally developed on each side." This condition may suffice to explain double neuritis but hardly can be considered satisfactory in monocular cases. Here we can more readily believe that a true rheumatic inflammation of the fibrous coat of the nerve between the optic foramen and the sclerotic opening, exists, caused by exposure, and that the inflammation is attended with a free exudation of serum and perhaps fibrin producing sufficient pressure to induce papillitis. Such cases are seldom fatal, and our pathology is at best speculative.

The purely rheumatic cases—*i. e.*, those due to exposure to draught or otherwise subjecting an overheated body to a sudden lowering of the temperature are generally monocular (Leber). Hence the exciting cause is probably an acute inflammation in the course of the nerve anterior to the chiasm; other causes—suppression of menses, of a purulent discharge, of perspiration of feet, absorption of poison, etc.—develop double neuritis. The hydrops is double and due to an abnormal collection of serum within the brain membranes.

Limitation of the field and peculiarities of loss of color perception are of little diagnostic or prognostic worth. The blindness comes on so suddenly and advances with such rapid strides that V. is lost before the patient is seen, or is so bad that the boundaries of the field are extremely uncertain. The diagnosis is at once decided by the ophthalmoscope. It shows through the clear media the engorged disk, its site marked only by exit and entrance of bloodvessels, its outline lost. A few small hemorrhages may be found, but they are rare, and no white patches of degenerative or choroidal atrophy are found. The pupils are dilated moderately or widely, and either not at all or only slightly responsive to light. The accommodation is presumably abolished. The sixth nerve may be involved in the paralysis.

The termination in the two new cases was recovery. It is not, however, always so favorable. In general the prognosis depends upon the site of the lesion and not on the degree of the amaurosis. When the hydrops is limited to the infraorbital part of the nerve the prognosis is favorable. When it is secondary to hydrocephalus, the patient either dies or recovers with partial or complete amaurosis.

In the treatment unanimity of opinion prevails—it consists in vigorous antiphlogistics; local and general bloodletting; the preparations or the alkaloid of jaborandi; mercury carried to salivation,

[1] Patient reappeared April 12th, on which day I made the following note in my case book: V = $\frac{20}{XXX}$ pty. Both nerves whitish, and small vessels absent; edges of disks moderately well defined. No patches in choroid or retina. Field and color perception normal.

and potassium iodide. I would especially call attention to the improvement of vision in my second case during the venesection.

254 South Sixteenth Street.

A RARE FORM OF MULTIPLE SARCOMA.

By WILLIAM G. PORTER, M.D.,
SURGEON TO THE PRESBYTERIAN AND PHILADELPHIA HOSPITALS,
AND
H. F. FORMAD, M.D.,
DEMONSTRATOR OF PATHOLOGY AND MORBID ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA.

John P. T., white, a native of the United States, married, a cabinet-maker, aged fifty-two years, admitted to Presbyterian Hospital July 4, 1884, had always been well until six years ago, when he first noticed a tumor, painless, and about the size of a marble, on the posterior and right side of the neck; this gradually grew, and when it was as large as a hen's egg, nineteen months ago, he was admitted to the Jefferson College Hospital, and it was removed by Dr. Allis; unfortunately no record of its microscopic character was preserved. The operation wound soon healed, and he remained well until four or five months ago, when he discovered a small tumor on the left side of the neck in the submaxillary region, and soon after another over the right pectoral muscle. On admission both tumors were found to be movable and not deeply seated. Their removal was advised, to which patient consented, but as he did not seem to be in very good condition, he was first given tonics, stimulants, and nourishing food.

He improved rapidly, and on the 23d of July the tumors were again carefully examined, when it was found that seven other tumors had developed. They varied in size from a filbert to a goose egg, were painless, superficially situated, and freely movable. The smaller growths were covered by normal skin, which was freely movable over them; as they increased in size they became adherent to the skin, and as they grew larger the cutaneous capillaries over them enlarged, and as they still further enlarged the skin over them gradually thinned and ulcerated.

The tumors were situated as follows: One in left submaxillary region, one over right chest anteriorly, one in right groin, one over body of each scapula, one over right buttock, two over left buttock, and one about the middle of the back. The one in the left submaxillary region had broken down, and bled easily on the removal of the dressings, as had also the one on the right buttock.

On the 24th of July, the submaxillary tumor, the tumor over the right buttock, and the one in the middle of the back, were removed; they were all superficially situated and encapsulated, and there was no hemorrhage of any consequence. The wounds were irrigated with a bichloride of mercury solution—1 to 1000, and dressed with lint soaked in a solution of the same strength. The tumors were all removed by circular incisions. The wound in the neck gaped widely, and was allowed to heal by granulation; the edges of the others were approximated by sutures, and they healed almost by the first intention.

On the 10th of August, seventeen days after my first operation, another tumor was found to be developing in the right temporal region. It was painless, and the patient did not know of its existence until his attention was directed to it. On the 13th of August, the tumor over the right pectoral region, which had now attained the size of an orange, was removed; it presented the same characteristics as the previous ones, and at the same time a smaller tumor the size of a hickory-nut which was situated about two inches below the outer extremity of the right clavicle was removed. Also one the size of a large orange from over the right scapula. The wounds were united by silk sutures, and treated as before, with equally good results. On the 28th of August, a new tumor was discovered near the lower and posterior border of the right axilla.

On the 30th of September, I again removed three more tumors with an enlarged inguinal gland. One tumor was in the right inguinal region, was the size of a large apple, and after its removal through a longitudinal incision, there was removed from beneath it, and through the same incision, an enlarged lymphatic gland about the size of a walnut. The second tumor was the one in the right temporal region before alluded to; it had increased considerably in size, was more deeply situated, and was immovable. Some difficulty was experienced in removing it, as its capsule was thin, adherent to the bone, and ruptured while being enucleated. It had to be extracted piecemeal; its contents were soft, of brain-like consistence. The third tumor was over the left buttock, and about the size of a fifty cent piece. After this operation the patient had some slight constitutional reaction, and the right eyelids and side of the face were considerably swollen for several days, but the maximum temperature reached was 100°, and he rapidly convalesced.

On the 17th of October, the patient developed malarial symptoms, and his general health began to decline. The tumors continued to increase in size, new ones were constantly developed, and at the time of his death, on February 20th, there were seventy-nine tumors scattered over the surface of his body.

Post-mortem examination seventeen hours after death, by Dr. H. F. Formad. Body greatly emaciated, skin very anæmic, and subcutaneous adipose tissue nearly all atrophied. The subcutaneous tumors have increased in size and number, and protrude as variously sized tubers upon the surface of the body. They are all covered by unimpaired skin. In size they vary from that of a pea to that of a large fist, the smaller ones predominating. Total number of neoplasms counted, seventy-nine. All the tumors appear as distinctly encapsulated nodes moderately firm in consistence; on section, white in color and yielding a clear blood-tinged juice upon being scraped with a knife. The tumors that had been formerly removed and had recurred were larger than the rest, and showed adhesions to the skin and surrounding structures and peripheral infiltration. The most conspicuous neoplasm was on the right temporal region and side of face, extending inward to the angle of the submaxillary bone. On dissecting it out, the base was found closely adher-

ent to the periosteum, the bone being eroded in some places. The upper edge of the zygomatic process was absorbed. All the tissues in the region between the bone and the skin were involved or absorbed by the new growth, which presented, when extirpated, an irregular shaped mass weighing thirteen ounces. The next largest tumor was extirpated from the left axillary space; it appeared to have developed from the fascia, and did not implicate the axillary lymph glands.

Thorax.—The pleural cavities contained, each, about three ounces of straw-colored liquid. A few old adhesions were noted at right apex. A small node of the new growth, about the size of a marble, was found in the parietal serous lining of the thorax in the third intercostal space on the left side near the spine. The bronchial and mediastinal lymph glands were enlarged, but did not appear to be infiltrated by the new growth. No tumor deposits could be discovered in the lungs; the latter were highly congested and œdematous, and somewhat hepatized in the lower lobes on both sides. The heart and pericardium were also free from tumor deposits.

Abdomen.—The liver is somewhat enlarged; weight, four pounds and five ounces. The left lobe of the organ was almost entirely replaced by a mass the size of a large fist, circumscribed, nodulated, and in other characters identical with the subcutaneous tumors. The right lobe of the liver was of normal appearance, but showed a few small nodes at the periphery, and on section exhibited a deposit of the size of a hen's egg in the interior. In the mucous membrane of the gall-bladder a flat deposit of the size of a marble was also found. About twenty pediculated masses of the new formation, varying in size, were found throughout and springing from the serous lining of the peritoneal cavity. The largest, in size corresponding to a hen's egg, was one hanging from the under surface of the diaphragm and wedged in between the latter and the liver. A number of these polyp-shaped deposits were attached to the omentum, the abdominal walls, the mesentery, and mesocolon, but it was not apparent that they involved the lymph glands. Some of the latter were merely hypertrophied to a moderate degree.

The kidneys were of normal size and appearance, but were the seat of numerous deposits of the new growth. Some of the nodes were located in the capsules of the kidneys, most of them, however, in the interior of the organs. A few hemorrhagic infarcts were noted in the cortex of the left kidney. Finally, some tumor deposits were found in the jejunum about its middle, springing from below the mucous membrane and protruding like mushrooms into the lumen of the gut. They were four in number, of the size of hickory-nuts, flat, and resting upon broad pedicles. Between two of the tumors the intestines showed a very perfect intussusception, which, from appearances, must have been of post-mortem origin. All the rest of the abdominal organs were normal.

The Brain.—No trace of tumor deposits, and no hemorrhage was observed. On examination of the base of the skull, it was found that the tumor described as involving the right side of the head penetrated through the right wing of the sphenoid bone, and a mass as large as a walnut was found inside of the dura mater, having forced its way from without into the cranial cavity.

Microscopical Examination.—A number of the tumors, and from all the various locations of the body were examined microscopically, and showed invariably the structure of spindle-celled sarcoma, large-celled variety. Their origin everywhere in the body was exclusively the connective tissue substances. The superficial neoplasms had taken their departure from the subcutaneous tissues and the fasciæ, those of the intestines from the submucous tissue, those of the abdominal cavity from the peritoneum, and those of the other parenchymatous organs from the interstitial connective tissue. The epithelial elements nowhere participated actively in the new formations. The mode of development and growth of the neoplasm has everywhere been originally a central one—*i. e.*, in the form of encapsulated nodes, though some of the tumors which had attained large size showed a peripheral growth by means of infiltrating the surrounding structures.

Remarks.—A close study of this case reveals some interesting and rather unusual features. The microscopical examination proved that every tumor in the body showed the structure of a pure spindle-celled sarcoma of the large-celled variety. It is, however, well known that the spindle-celled variety of sarcoma, although malignant so far as recurrence *in loco* after extirpation is concerned, does not give metastases to internal organs. Further, it is also known that tumor metastasis does not affect the skin, nor are malignant tumors known to travel from one part of the skin to another (unless by direct continuity and uninterruptedly). All the tumors in the internal organs in this case, as well as every one of the many isolated tumors in the subcutaneous tissue, must consequently have been of independent origin, and must have each started from independent foci of their own. Moreover, the tumors could not be traced to have spread either by continuity of structures or by the blood or lymph channels. It appears to be evident that we deal here with a tumor dyscrasia, viz., a case of true multiple tumor disease unusual especially for the spindle-celled variety of sarcoma, and not with the metastatic form of sarcoma.

SARCOMA OF THE ORBIT:

REPEATED REMOVALS; NON-RECURRENCE FOR EIGHT MONTHS.

By D. C. COCKS, M.D.,
CONSULTING OPHTHALMIC SURGEON TO THE RANDALLS' ISLAND HOSPITALS, AND ASSISTANT SURGEON TO THE NEW YORK EYE AND EAR INFIRMARY.

I was invited by Dr. J. H. Fenner, on the 5th of April, 1885, to see a daughter of Mr. C., of Harlem, in consultation. The patient was about four years old; the family history revealed the fact that her grandfather had had a "sore" (epithelial?) at the inner canthus. Six weeks before (Feb. 1885), the family first noticed a swelling of the upper eyelid of

the right eye in the granddaughter, and it had gradually increased and now demanded attention.

Present condition: She is apparently in perfect health, and is well developed for her years. The left eye is normal in all respects. The right eye presents the appearance of ptosis, but the drooping of the eyelid is found to be due to a swelling under the upper eyelid. The eye is also forced downward and outward by the same agency. The movements of the globe are not limited by the size of the growth. Sight is normal. On palpation the growth is found to be a hard, bilobular tumor, movable in the orbit, unattached to the skin, and having slight if any adhesions to the orbital walls. It is the size of and has the "feel" of two small hazelnuts in juxtaposition. The density and rapidity of the growth gave indications of malignancy, and its immediate removal was advised.

The following day, chloroform having been administered, I made a horizontal incision one inch in length through the upper lid, about three or four lines above the upper border of the cartilage, down to the growth. As it had made a capsule for itself of the connective tissue of the orbit, I easily separated it from its connections in front with the handle of my scalpel and blunt hooks. A strong silk ligature was then passed through the tumor by which it was drawn forward, and the enucleation proceeded with. I succeeded in loosening the whole growth in this manner except at its upper border, where a fibrous attachment to the periosteum required the use of scissors.

The operation was done with antiseptic precautions, and the wound healed by first intention except at the inner angle, which required a few days for cicatrization to be complete. The tumor when removed was about the size of a horse chestnut, and was of the consistency of a fibroid on section. Microscopically it was pronounced by Dr. J. L. Minor (now of Memphis), and Dr. J. B. Campbell, of New York, to be a small round-celled sarcoma.

April 27. Patient can open the eyelid fully, but it is retracted at the inner angle.

May 5. Yesterday I noticed a hard and tender lump at the inner angle of the orbit. The lid is again slightly swollen.

6th. The new growth has the same feeling as the primary tumor. It is situated a little nearer the inner angle. A consultation being held, it was determined (taking into consideration the microscopical appearance of the primary growth and the rapidity of its redevelopment) that the new growth should at once be removed together with its periosteal attachments, and as much of the surrounding bone as was safe to take away.

Accordingly, on May 8th, assisted by Drs. Fenner, McLean, Peirce, G. H. Cocks, and by G. Marshall, D.D.S., I made an incision two inches long parallel to and just above the eyebrow, also one at right angle to this from the bridge of the nose up to the forehead for about one inch. These flaps were then dissected up and reflected respectively upward and downward, freely exposing the growth and its attachments. With the aid of a dental engine, a dental burr was used to cut through the periosteum and to make a groove two lines in depth around the growth (which was attached to the bone). I then moved the burr gradually from the periphery of the circle thus made toward its centre; as the burr advanced, it removed everything in its path for at least one-eighth of an inch below the periosteum. The growth and its base having thus been gotten rid of, I proceeded to remove all of the suspicious tissue in the vicinity and in doing so removed at least a square inch of periosteum from the roof of the orbit, the eye being depressed to allow the burr to enter the orbit freely.

All this having been done antiseptically, the edges of the wound were coaptated, and a pressure bandage applied, which was allowed to remain for one week. No reaction followed, and when the bandage was removed the wound was found to have healed throughout by first intention. A slight serous discharge, however, showed itself from the inner angle of the wound three days later, but lasted only about two days.

I felt at this time that I had thoroughly eradicated the diseased tissue, but in three weeks time the growth reappeared, and the following week was seen to project into the superior cul-de-sac of the conjunctiva. Then in view of its evident malignancy, and although the globe was not involved, I advised evisceration of the orbit, which was done in June. From this last operation the child made a good recovery, and remained free from any local recurrence until her death, which occurred in February, 1886, from pneumonia following measles one year after the growth was first noticed, and eight months after the evisceration of the orbit.

The points of interest in the case are:

1. The repeated recurrence of this orbital growth after apparently thorough removal of all diseased tissue.

2. Its non-reappearance after the removal of *all* the tissue that could possibly contain any disease germs.

3. Many will question the propriety of the removal of an eye when not involved in the disease, but I was and am convinced that in no other way could immunity be obtained *in this case*, as the second operation was as thorough and extensive as *I* could make without sacrificing the globe, and *it failed.*

4. Although the growth *might* have recurred had the child lived, it certainly was saved much suffering by its removal.

5. This case emphasizes the fact that recurrent growths in this region can only be successfully dealt with by the use of most energetic measures.

HOSPITAL NOTES.

ST. MARY'S HOSPITAL, QUINCY, ILL.

Service of Dr. William A. Byrd.

(Reported by Alexander F. Lee, M.D.)

INGUINAL COLOTOMY.

John W., colored, æt. forty years, was admitted to hospital December 12, 1885, suffering from some obscure hip trouble. For several months prior to his admission he had suffered from pain, gradually increasing in severity, in and about the left hip-joint. This he attrib-

uted to rheumatism, and he had been treated for that disease, but with no amelioration of the distressing symptoms. Had been having fever, varying in intensity, with occasional night sweats. There was also a history of rectal trouble. Tongue was considerably coated. Breath offensive. Appetite poor. Constipation alternating with diarrhœa, with some pain during defecation. On examination the left hip was observed to be considerably enlarged, emphysematous, and painful on pressure, with slight flexion and adduction of the thigh.

Perforation of the rectum was diagnosticated, the pus passing out of the pelvic cavity through the great sciatic foramen and burrowing into the hip. This caused irritation of the nerves and muscles of the hip, and accounted for the hip symptoms.

The patient was placed upon tonic treatment, and the following week several long and deep incisions were made into the hip, evacuating a large quantity of pus having a fecal odor. Considerable extremely offensive gas escaped at the same time with a hissing sound. For several weeks after this the patient improved steadily. The abscesses were washed out daily, and the tonic treatment was continued.

The improvement, however, was only temporary. The fever and night sweats recurring, the pulse being rapid and weak, the patient growing thinner and weaker, and the discharge from the abscesses becoming *feculent*, showing conclusively a communication with the bowel, it was determined, as a *dernier ressort*, to give the bowel rest, and permit the healing of the abscesses by performing colotomy.

January 30th, the patient was anæsthetized with a mixture composed of one part by measure of bromide of ethyl, three of chloroform, and four of alcohol. Believing inguinal colotomy preferable to lumbo-colotomy because the discharge coming out in front would be under better control of the patient and attendants, and would not be as irritating as at the back, an incision to the extent of about three inches was made one inch above and parallel to Poupart's ligament. Entering the abdominal cavity the sigmoid flexure was sought for, brought external to the opening, ligated, and divided below the ligature. The opening in the lower portion of the bowel was closed by sutures, and united to the inferior angle of the incision for future use. The circumference of the upper portion was now united by sutures to the edges of the incision, being careful to enclose the parietal layer of the peritoneum, thereby uniting peritoneum to peritoneum, and establishing an artificial anus.

The ligature was now removed, and the patient sent to his ward. Opiates were administered to prevent and control peritonitis. Since the operation there has been some peritonitis with the accompanying symptoms, hiccough, etc. The feces pass through the artificial anus and cause very little trouble or inconvenience to the patient. By means of a syringe passed into the rectum, not only is the rectum washed out but also the sinuses in the hip, showing an undeniable communication. The patient exhibits marked improvement and the abscesses are daily becoming smaller, with the probability of their soon closing.

Remarks.—As will be seen from the history of this case, there was considerable difficulty in making a diagnosis, and arriving at the true cause of the hip trouble. The patient had been treated for rheumatism; the same symptoms might have arisen from hip-joint disease or resulted from psoas abscess.

Knowing that there was a communication with the rectum, and that so long as the feces were permitted to pass through the bowel and out into the sinus, just so long would the bowel refuse to heal, and as a natural consequence the sinuses and abscesses in the hip also; knowing this, one principal object in the treatment must be attained, rest for the bowel. Rest was the *sine qua non*, and there was but one means of obtaining it for the requisite time—performing colotomy and compelling the feces to make an abnormal exit until the bowel could heal.

It is not the intention to leave the artificial anus permanently open. As soon as the abscesses and sinuses in the hip shall have healed, the opening into the bowel closed, and bowel attained healthy condition, then, and not till then will the artificial anus be closed, and the divided gut reunited. Of course, this necessitates a second operation, with the danger of peritonitis, etc., but the great benefit to be derived from closing the artificial anus and permitting the feces again to seek their natural channel, is sufficient argument in its favor.

MEDICAL PROGRESS.

Spartein.—MM. Laborde and Legris, in an article entitled "La Méthode Expérimentale appliquée à l'Étude des Substances Médicamenteuses," published in the May number of the *Archives de Physiologie Normale et Pathologique*, come to the following conclusions concerning spartein. Spartein renders the heart-beats stronger and more protracted; its action on this organ is essentially dynamogenic and central in origin. Absence of alteration in pressure and of peripheral or vasomotor effects constitutes one of the important proofs, and is corroborated by other phenomena; among them those belonging to convulsions and asphyxiation, which indicate a predominant influence of the medulla oblongata and spinal cord. It must always be remembered that in frogs, a long time after actual death, even when the animal begins to dry, the heart beats rhythmically, as though spartein gave an impetus to the strength and length of the beats. MM. Laborde and Legris observed similar phenomena in newborn puppies. No other influence proceeding from the nervous system can be supposed to act in this case than that of intracardiac ganglia. The myographic researches made by these investigators have not at present furnished results that warrant decided conclusions.

The therapeutic properties of spartein were formulated by M. Sée, in his paper to the *Académie des Sciences*, as follows: It revives the heart-beats and the pulse; in this respect it equals in action digitalis and convallamarine, the alkaloid of lilies of the valley. As a tonic it is more active, more prompt, and more lasting It immediately regulates the rhythm in cardiac disturbance; in this effect it is superior to any other medical substance. In serious atonic conditions the heart-beats are quickened, and in this respect spartein resembles belladonna. The favorable modifications resulting from the action of spartein occur in one hour, or in some cases a few hours after its administration, and continue two or three days,

when its use is discontinued. During this time the general strength is increased, and respiration is rendered easier, but not so effectually as by potassium iodide. The urinary function is not influenced by such small doses as those hitherto used. The more recent researches made by MM. Laborde and Legris lead them to endorse M. Sée's statements, and they further state that the action of spartein is quicker and more rapid than M. Sée observed it to be. A daily dose of sulphate of spartein varies from five to twenty-five centigrammes.

The prompt action of spartein renders it invaluable in heart-disturbance requiring immediate treatment; in instances of asystolia its use is preferable to that of any other drug. In all cases of weak heart with asthenia, sulphate of spartein should be used, whether there be lesion or not. MM. Laborde and Legris declare that they do not know any conditions that should be regarded as indications against the use of spartein; it is not an accumulative substance in small doses, it does not exercise a deleterious effect either on the digestive organs or on the cerebrospinal system. It can be used for some time without an interruption being necessary. When digitalis is used, in the necessary intervals of administering it spartein sulphate may be given with advantage. In cardiac affections accompanied with dropsy, an infusion of broom-flowers added to spartein sulphate has a beneficial effect, acting as a diuretic. In cardiac dyspnœa, iodide of potassium may be used as well as spartein sulphate, and pyridin inhalations should also be administered.—*London Med. Record*, July 15, 1886.

Atropine Poisoning.—Kratter, in the *Vierteljahrsschrift für Gerichtliche Medicin*, XLIV., S. 52, contributes a long paper on poisoning by atropine, based on a study of eight cases in his own experience. The following are his conclusions:

1. The detection of atropine in the body is certain, provided proper methods of analysis are employed.

2. The urine is especially valuable for this purpose, since atropine is quickly absorbed and entirely excreted through the kidneys, apparently without undergoing change. It can be detected in the urine in cases which have not terminated fatally.

3. The examination of the pure crystalline residue in polarized light, though not conclusive, is to be recommended, since the crystals of the sulphate are sufficiently characteristic to render the detection of atropine in this way tolerably sure.

4. Positive proof of the presence of atropine is only to be found in its physiological action. The human eye is best of all for this purpose, since it is the most sensitive. The eye of the cat is also very sensitive.

5. Atropine shows great resistance to putrefactive processes, and can be detected in bodies which have been buried for some months.

6. Owing to the rapid elimination of atropine through the kidneys, the results of the chemical analysis are liable to be negative if the patient survive for some days.

Flückiger, in the *American Journal of Pharmacy* for April, 1886, p. 198, confirms the observation made by Mr. A. W. Gerrard in 1884, that the mydriatic alkaloids are possessed of quite exceptional alkaline power toward mercuric chloride, from the aqueous solution of which they precipitate mercuric oxide, the other natural alkaloids giving no precipitate at all with mercuric chloride, or, at least, in no case separating mercuric oxide.

Flückiger now makes the further observation that atropine, quite exceptionally, is able to impart a red coloration to phenolphtaleïn paper, thus contradicting the assertion made by him in 1884, that alkaloids generally were deprived of such an action. He has demonstrated that atropine is the only alkaloid (speaking, however, of the more generally used alkaloids) which displays the same action as the inorganic alkalies. This is a remarkable coincidence, and goes far to favor the suggestion that atropine must be peculiarly constituted, differing from other solid alkaloids, none of which, so far as we actually know, show the same behavior toward mercuric chloride and phenolphtaleïn. The author has also tried other coloring matters, and found them to be acted upon by atropine in the same way as by potash and soda. Atropine, therefore, has an alkaline power like the hydrates of sodium and potassium, differing in this respect from (probably all) other alkaloids. The author states, however, that mercurous chloride is not blackened by atropine as it is by the alkaline hydrates. Mr. Gerrard, *Ib.*, on the other hand, asserts that this statement is contrary to fact, and he has placed on record the experiments on which his assertion is based.

Flückiger describes modifications of the other tests for atropine. The original paper is referred to for details. It is to be borne in mind that phenolphtaleïn can be used in the identification of atropine only in the absence of the inorganic alkalies.—*Boston Med. and Surg. Journal*, July 29, 1886.

Alcohol in Hospitals.—Dr. Drysdale, leading physician of the Metropolitan Free Hospital of London, England, lately read a paper before the British Medical Temperance Association on the above topic, in which the following conclusions were prominent:

1. Alcohol is not a real food, but must be classed among the anæsthetics, in company with ether and chloroform; hence it ought not to be used as an article of ordinary diet.

2. The treatment of fevers by alcohol in large quantities is inferior to the treatment by cold and ordinary diet.

3. There is no clear proof that alcohol is changed into carbonic acid and water in the system; and, at any rate, part of it remains unchanged for as much as twelve hours in the system, irritating the internal organs.

4. Moderate amounts of alcohol neither raise nor lower the temperature, but excite the heart's action, and in some cases, in small doses, less than one ounce gives appetite.

5. In large and stupefying doses, alcohol lowers the temperature.

6. The amount of alcohol administered in various hospitals is so wanting in uniformity as to show that there is no settled opinion in the profession at present as to its value.

7. It would be well, when alcohol is prescribed in clinical hospitals, that some exact amount of it should be prescribed, and not a varying amount of an alcoholic fluid not analyzed.

8. The London Temperance Hospital experiment seems to indicate that many diseases do well without the use of any alcohol, which previously were thought to require it.

9. Hence, whilst the modesty of science forbids us to say that alcohol will prove useless in any given disease, it seems advisable for patients in hospitals to have that drug administered to them with far greater caution than has hitherto been the case. And it would seem also to follow that all mere dietaries should be free from the routine use of alcohol, which should in all cases in hospitals be distinctly ordered to the patient by his medical adviser.—*Quarterly Journal of Inebriety*, July, 1886.

A Contribution to the Comparative Study of Convulsions.—An elaborate article by Hughlings-Jackson, which appeared in *Brain*, for April, 1886, is analyzed as follows in *The Manchester Medical Chronicle* for June, 1886.

On a review of the manifold phenomena included in the familiar terms "fits" and "convulsions," the author comes to the conclusion that they may be divided into three great classes, according to the regions of the central nervous system from which they take origin. These regions he regards as forming three groups of centres classified, in order of evolution, as lowest, middle, and highest sensori-motor centres. The lowest centres are those lying in the spinal cord, medulla, and pons, with some others, reaching as high as the centre for ocular movements; the middle "level of evolution" includes Hitzig and Ferrier's motor centres, Schäfer and Horsley's trunk centres, and Ferrier's sensory region; while the highest level consists of parts of the brain in front of the middle motor centres, with the highest motor centres, and the highest sensory centres lying in the occipital lobes. All parts of the body are represented by each order of centres, in simplest, more complex, and most complex combinations respectively. To the highest level of all are referred epileptic convulsions (true epilepsy), to the middle level epileptiform seizures, and to the parts lying at the lowest level "inward fits" or respiratory convulsions.

After laying down these general principles, the author concentrates his attention, throughout the rest of the paper, on the convulsions (respiratory convulsions) of very young children. These fits occur, as he points out, almost exclusively within the first year of life, a highly momentous period of the brain's existence. The two higher levels are as yet unevolved, while the centres of the lowest level are rapidly developing, those for the organic functions naturally taking precedence of the others in point of time. Thus, at one epoch of life, the respiratory centre, for example, will be "at once undeveloped and actively developing," and, therefore, highly excitable and unstable. At the same time, the higher regulative mechanisms, which will afterward repress exuberant discharge, are still practically non-existent.

Here, then, we have a condition favorable to the easy provocation of excessive respiratory efforts.

Again, as the author shows, a motor centre suddenly goaded into excessive and rapid discharge will tend to sum up the several movements under its sway, to produce them no longer in their natural alternation but coëtaneously; so that opposing groups of muscles will finally pass from harmonious working into violent contention—into that condition, namely, which we recognize as a convulsion. Moreover, the convulsions, at first confined to the muscles employed in normal respiration, will gradually spread to the auxiliary muscles, and thence, by secondary excitation of neighboring motor centres, to most of the muscles of the body.

The fact that rickety infants are above all liable to these fits appears to Dr. Hughlings-Jackson to point to their true pathology. The softness of the ribs in rickets deprives the diaphragm of its normal support, and seriously embarrasses respiration. The respiratory centre is thus perpetually bathed in blood so highly venous that it requires only a slight additional stimulus to throw it into furious action. A coughing fit, for example, will, by checking the already imperfect respiration, decide the onset of a convulsion.

This theory is supported, in his opinion, by the fact that similar convulsions occur in rapidly asphyxiated animals, and in children the subjects of laryngitis, or cyanosed from congenital heart disease. Further countenance is given to it by the success of the treatment usually adopted for cases of laryngismus. Cold sponging, removal to a purer or even to a colder air, and such drugs as musk, belladonna, etc., are all stimulants of the respiratory centre, and find their chief value in reducing the persistent venosity of the blood.

The paper concludes with some remarks on "eccentric irritations," which the author believes to be powerless of themselves to start convulsions; they are important only as determining an explosion for which the centre has been prepared by a more potent agency.

The Microbes of Pneumonia.—The subject of acute pneumonia is one of those which of late has excited a considerable amount of attention, and yet, common as the disease is, it is one which is surrounded by many unsolved problems Professor Weichselbaum has recently contributed to the Vienna Medical Society a paper, in which, after stating the prevalent opinions upon the nature of the affection, and dwelling especially upon the different opinions held by Friedländer on the one hand and Fränkel on the other as to the precise characters and properties of the supposed bacterial agent, he relates his own experiences. He points out that clinicians are divided into two camps upon the etiological question, some regarding pneumonia as solely an infective disorder, others considering that the infective forms are different from those caused by exposure to cold. Weichselbaum, distinguishing between primary and secondary forms, divides them into (1) lobar; (2) disseminated; (3) passive pneumonia—hypostatic, etc.; and (4) lobular. He has examined 127 cases and instituted 87 cultivation experiments, the material for the cultures being obtained one or two hours after death, as well as from the living subject, by means of a Pravaz syringe introduced into the lung and pleura. He distinguishes four kinds of microörganisms. The diplococcus pneumoniæ is the most common, consisting of oval, elliptical, and round cocci, which occur in chains as well as in pairs. The chains are composed of from six to eight or as many as twenty to thirty cocci, are straight or slightly curved, and the cocci are developed in a capsule of varying thickness in proportion to their vitality. The second variety resembles the first,

but distinguished by a greater uniformity in spherical shape, and in forming long and sinuous chains. The third is known as the Staphylococcus aureus s. albus. The fourth he terms the bacillus pneumoniæ, consisting of rods of different lengths, the smallest and apparently youngest being oval. They have a capsule, and correspond to Friedländer's pneumococcus. The first variety was found in ninety-one cases, mostly of croupous pneumonia, also in the secondary forms. The second, or streptococcus, was found twenty times—namely, in fifteen cases of primary and five of secondary pneumonia. The staphylococcus occurred in secondary cases only, and mostly where the primary disease was due to this microörganism. The fourth kind was met with nine times, four times unmixed with other forms. All these organisms were most abundant in the earlier stages of the disease, being scanty or absent in gray hepatization, and, if present, staining badly or unencapsuled. At the margins of the pneumonic focus in the œdematous tissue micrococci were numerous, pointing to the œdema being not a passive process but a precursory stage of pneumonic infiltration, and resembling the invasion of cutaneous tissue in erysipelas. Moreover, inflammatory changes accompanied by these microörganisms were found in the respiratory tract above the lungs. Secondary meningitis in pneumonia was shown to be due to the presence of the same microorganisms, which were also found in the serous exudations of pleurisy and pericarditis, which might complicate the lung affection. The bacterial origin of the disease was, therefore, held to be demonstrated.—*Lancet*, June 12, 1886.

POISON BY RAT BITES.—In an article thus entitled, in the *American Practitioner and News* for July 24, 1886, DR. A. J. BANKER records in full five such cases. He says: "I have collected cases to the number of ten; the full notes of some I have not yet been able to obtain. Out of the number, four have died; two with dropsy, one with tetanus, and one with extensive sloughing and so-called pyæmia. The history of the cases is, in the main, the same, the stage of incubation varying but a few days. In most of the cases the wound healed kindly without general disturbance, and the general disturbance which came on subsequently seemed to be in the nerve-centres.

"In each of these cases a particular train of symptoms was developed, bearing a relation in a collection of cases which suggests the idea of a specific poison. The question now arises, Is this form of poison specific in its character, or does it belong to that general class of blood poisoning denominated pyæmia and septicæmia? As to the treatment which seems best adapted to the poison, I have been unable to arrive at any definite course. The only fact which impressed itself forcibly upon my mind was the intolerance of the patient to any medicine containing acid. The muriated tincture of iron acted as an excitant and aggravated the nervous symptoms, besides it had a deleterious effect on the secretions. Alkalies are well borne in the acute stages, and alleviate the sufferings and favor elimination. Salicylate of soda with acetate of potassium, or large doses of bicarbonate of soda, act favorably. A thorough saturation of the blood with alkalies seems to counteract the poison."

DOVER'S POWDER AND ITS MODIFICATIONS.—"If I could envy any one, as a therapeutist, it would be the old physician who originally had the happy thought of blending astringent opium with relaxant ipecacuanha, and both with a diuretic and laxative. I suspect that Dover's name, though so little is known of the man himself, is more frequently quoted than that of any other physician. This by the way; that which I have in my mind is to suggest that it is often very good practice to modify Dover's powder by combining the one grain of opium and the one grain of ipecacuanha with other salines than sulphate of potassa. The true Dover's powder contains nitrate of potassa as well as sulphate, four grains of the nitrate to four of the sulphate, and it often seems to me reasonable to revert to this form, the nitrate of potassa being, in small doses, a good diuretic. I also very often venture to prescribe the powder with other modifications of the saline part, and with advantage. In acute rheumatic fever I usually substitute sodium salicylate for the potash salt; in gout, bicarbonate of soda; in remittent febrile cases, two grains of quinine with five of sodium salicylate; and in tonsillitis and other febrile throat affections, chlorate of potassa. It would surely be worth the time and skill of one of our scientific pharmaceutical brethren to prepare and bring out a series of Dover's powders in these modified forms."—DR. B. W. RICHARDSON, in *The Asclepiad*.

TREATMENT OF HYSTERIA BY COMPRESSION OF NERVES.—DR. RUAULT, in a communication to the Clinical Society of Paris, recommends, for the arrest of an hysterical attack, compression of a superficial nerve trunk, especially at its point of emergence from the deep parts. When firm pressure is made on both supraorbital nerves (the ones most easily got at), kept up for sufficient length of time, and directed to one point of the nerves, the patient's face soon takes on an expression of pain, several short inspirations are taken in rapid succession, followed by a deep expiration, and the fit is over. Dr. Ruault has thus, during the past four years, almost invariably succeeded in cutting short hysterical attacks, including hysterical dyspnœa, hysterical delirium, etc.—*Glasgow Medical Journal*, June, 1886.

EXPERIMENTS IN GASTRIC DIGESTION.—BIKFALVI maintains that in flesh-eating animals the chief function of gastric digestion lies in the dissolution of connective tissue and other collagenetic substances; while the digestion of albuminoids is chiefly effected by the pancreatic juice. He finds by experiments on dogs that in two hours of gastric digestion the following percentages of given substances are digested:

Raw cascin	25 per cent.
Boiled egg albumen	41 "
Raw ligam. nuchæ	49.5 "
Raw liver	52.5 "
Raw kidney	55.33 "
Boiled beef	58 "
Raw unstriped muscle fibre	68.5 "
Raw beef	79.5 "
Raw hyaline cartilage	81 "
Raw fibrin	97.5 "
Raw lungs	99.5 "
Raw tendons	95.5 "

—*Centralbl. f. d. med. Wiss.*, No. 7, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 7, 1886.

THE NATURE OF TETANUS.

NEXT to hydrophobia tetanus is, probably, the most obscure subject in the field of surgery. The explanations of its nature which have yet been offered or accepted, have not been entirely satisfactory, nor have they led to any good understanding of the principles of treatment of this fortunately rare disorder. The nervous theory has much in its favor; but it cannot be said to be competent. The zymotic theory is, to some minds, no more so. To those who have witnessed a number of cases of tetanus any explanation of its nature will probably be less satisfactory than it would be to those who have formed their ideas of it from reading. Circumstances peculiar to individual cases often seem inconsistent with any one of the theories thus far offered as to the nature of this disorder. And yet something is being done from time to time to elucidate this obscure subject.

The latest contribution with this object is a communication of ROSENBACH, of Göttingen, to the Fifteenth Congress of German Surgeons, in which the germ theory of tetanus is supported. Many experimental attempts to convey tetanus from man to animals have proved unsuccessful. Carle and Rattone first succeeded in producing tetanus by inoculation of the contents of an acne pustule. The results were positive in eleven out of twelve rabbits. Nicolaier inoculated rabbits with earth, and in a number of cases produced, in addition to malignant œdema, a set of symptoms which resembled those of tetanus. Rosenbach attempted to come much closer to the nature of tetanus by securing inoculation material from a patient suffering with tetanus after having had his feet frozen. This material was taken from the part below the line of demarcation, and was inoculated into two guinea-pigs, which showed symptoms of tetanus the next day, and died in the course of it. Taking new material from the point of inoculation in these animals, Rosenbach succeeded in producing similar symptoms in four guinea-pigs and eleven mice. This tetanus was, apparently, identical with Nicolaier's earth tetanus. The most marked symptom was spasm of the extensors of the tail and of the hind legs.

The location of the first symptom depended upon the seat of the inoculation. If this were made in the loin, the corresponding leg became stiff, the foot spasmodically extended, the tail rigid and inclined toward the inoculated side; and similar symptoms soon followed on the opposite side. After this the muscles of the lower part of the back were affected, and then those of the anterior extremity, and of the jaw. Trismus and opisthotonus followed, and in about twenty-four hours the subjects of experiment died in pronounced muscular tonus. If the inoculation was practised on the anterior extremity the symptoms began in it, with spasmodic extension and pronation; and trismus soon followed. In these cases the body was flexed toward the side on which the inoculation was made, in a state of pleurosthotonus. In all cases there was first a local and then a general state of tonic muscular spasm.

Rosenbach discovered in the inoculation material which he used a delicate bristle-shaped bacillus, similar to that described as the cause of earth tetanus. This he successfully cultivated in coagulated serum, and found the fourth generation as efficient as the first. Under cultivation the bacillus developed a spore at one end, and came to resemble a pin or drum-stick in shape. In endeavoring to isolate this bacillus, Rosenbach got no further than to obtain it in conjunction with the bacterium of putrefaction. But, as the latter alone does not produce tetanus, it seems to him proper to attribute to the former the tetanus which follows the inoculation of both together. He also thinks that this experimental result is important from its correspondence with the fact that tetanus in human beings is apt to follow putrefactive wounds. In regard to the mode of propagation of this bacillus, and of infection of the whole system, Nicolaier has made a number of experiments, and has detected the bacillus once in the sciatic nerve and twice in the spinal cord, and Rosenbach found it in the latter situation twice.

In the discussion upon this communication, KÖNIG confirmed the identity of the experimental tetanus of Rosenbach and of Nicolaier with that of human beings, and that which frequently occurs in horses after castration. In these the spasms often

begin in the muscles of the extremities and back; and so, in human beings, trismus is not always the first evidence of tetanus. SOCIN reported that he had also produced genuine tetanus with inoculations of garden earth. EBERMANN called attention to the possible influence of ptomaïnes in the production of tetanus.

This interesting presentation of the subject of the pathogenesis of tetanus contains some assertions which cannot be admitted without question. In the first place, it is not true that tetanus is more apt to follow wounds in which putrefactive changes occur. On the contrary, the experience of most surgeons is that no sort of wound or injury is specially liable to cause tetanus, and it is a recognized fact that it is as likely to follow the most trifling injury as the most serious. This is as true of injuries of the nerves themselves, as it is of any other part. Again, it is decidedly exceptional to find the first manifestations of tetanus in muscles other than those of the neck or jaw. It is noticeable also, in a paper which maintains the germ theory of this disease, that the investigators who have been most successful in producing it experimentally have found the specific germ in only a small number of the cases, and then in ridiculously small numbers; and there is no mention of its ever having been found in the blood or nervous system of human beings.

It has not escaped the attention of Rosenbach that there seems to be a disparity between any conceivable rate of multiplication of germs within the body and the rapidity of the development of experimental tetanus. For an explanation of this he has to have recourse to the hypothesis of a ferment, such as belongs to the humoral theory of the nature of tetanus. This weak point in the germ theory we believe to be fatal, and we cannot see how it can be lightly passed over, or how Rosenbach can so innocently designate as an "incubation period," one which was no longer than twenty-four hours. The experiments reported are interesting, and deserving of careful study; but they are by no means conclusive. They may show that some lower animals are liable to tetanus after inoculation with irritants containing a certain bacillus; but it is well known that tetanus may occur in human beings in consequence of injuries in which the skin has not been broken. There is a case reported by Nicaise, in which it was produced by dashing a glass of cold water upon an infant. Then there are the cases of idiopathic tetanus, in which the presence of a bacillus can hardly be imagined, and those of trismus nascentium, usually attributed to tying the umbilical cord, a method hardly favorable to the entrance of germs. In fact, the nature of tetanus is almost as obscure to-day as that of hydrophobia, and the nervous theory still seems the most reasonable one in regard to it. In some cases it seems to be a disease caused by imitation. Not long ago there occurred two cases in a hospital in this city, in the second of which the disorder seemed to be of this sort. It is a curious fact that a large number of cases of tetanus have followed injuries received in celebrating the Fourth of July in certain cities in this country, so that there was a kind of epidemic, the number of cases being out of all proportion to the ratio of cases of tetanus in gunshot wounds in general. Such occurrences must be largely due to the prevailing fear of lockjaw at this time, although it might be supposed to be explained by the great heat of this season of the year.

It would be a great gain to science if we could discover the *materies morbi* in tetanus, and a great gain to humanity if we could learn how to forestall its action. But we have not got so far yet; and the germ theorists may or may not be on the right track. Further experiments with inoculation of different materials may clear the subject up, if they are undertaken without bias, and carried out with rigid accuracy.

THE TREATMENT OF ERYSIPELAS.

So much has already been written on the subject of the treatment of erysipelas that it might seem superfluous to add anything to it. But from time to time the journals contain accounts of methods which have been so successful in the hands of those who recommend them that it seems surprising that they do not supersede all which have preceded them. This surprise, however, diminishes when it is borne in mind that a remedy which proves useful in one case of this disease may prove useless in the next, although the cases seem exactly alike. The general principles of the treatment of erysipelas are unfortunately sometimes overlooked in the zeal which champions some special method, and too much is attributed to what may have had but a small share in the cure, or neglect of these general principles leads to failure when a method of undoubted value is tried.

The attempt of Hueter to cure erysipelas by means of hypodermatic injections of solutions of carbolic acid, which has fallen into disuse, illustrates the error of following too blindly a special indication. The belief in the germ theory of this disease, which is quite general in Germany, led Hueter to hope that it could be cured by destroying the germs at the seat of the inflammation. In this, experience has shown that he was mistaken. The books indicate plainly by their contradictory statements that others have committed the same error of generalizing from too scanty premises. Thus, one author recommends the use of venesection, or blisters, or ointments, or washes, or powders, and another says that they do no good. Both statements accord with the experience of those who make them;

but it is evident that both cannot be of universal application.

It is not necessary to illustrate this point further. But, bearing it in mind, it may be possible to estimate properly the claim of special efficacy for any new or revived method. The most recent claim of this sort is made by Kühnast in the *Centralblatt für Chirurgie*, February 27, 1886, for the plan of multiple scarifications, followed by the application of carbolic acid solution. Kühnast's experience has been gathered in the clinic of Prof. Kraske, in Freiburg. Here a few cases of erysipelas have recently been treated very successfully in the way described. Acting upon the theory that erysipelas is a germ disease, and relying upon the investigations of Fehleisen, which seem to show that the coccus of this disease is found in and near the seat of evident inflammation, the practice of Hueter has been modified by making scarifications carried beyond the limit of the redness, squeezing out the accumulated fluids, and then rubbing in a five per cent. solution of carbolic acid, with the idea that the release of the accumulated fluids of the skin and subcutaneous tissue and the relief of tension would favor the access of the germicide to the germs. The development of this theory by Kühnast is interesting; but it is not materially different from the way in which the good effect of punctures or scarification was accounted for as long ago as 1828, when Sir R. Dobson advocated this method. Kühnast appears to attribute too much virtue to the antiseptic. His preference is for carbolic acid, but he has had to abandon it for corrosive sublimate in one case; and he very properly thinks that salicylic acid or boric acid may be more suitable in others.

There can be no question that very satisfactory results have been secured in a few cases by this method, but neither the experience nor the argument of Kühnast warrants the conclusion that it deserves any higher estimate than that it is a sensible plan for the treatment of certain cases. These seem to be cases seen early, before deep inflammation has occurred, in which the general condition of the patient is fairly good. But they are the very cases in which any one of many methods may prove useful, and in which most surgeons would hesitate to take such energetic steps to meet the disease. Still, it may be well to call attention once more to the value of local bloodletting and relief of tension in the bloodvessels and lymphatics to which Kühnast's cases bear witness; and to the value of dressing the little wounds made by the knife with material which shall exclude the possibility of a new infection. We are not disposed to attach much importance to the germicide action of any of the antiseptics recommended for this purpose; but they can do no harm, and they help in securing the purity of the dressings.

CHIARA'S PORRO CASES.

The eighth operation in the general Porro record, and the fourth of Italy, was that of Prof. Chiara, then attached to the Santa Caterina Maternity of Milan; this was in August, 1879. During his service in that hospital he operated five times, saving his last three cases, and all of the five children. After his removal to Florence, having been appointed to a professorship in its University, he became attached to the Maternity in that city, and resumed his obstetrical labors. Here, in July, 1884, he performed his sixth operation, which proved fatal from kidney disease. On January 13, 1885, he operated for the seventh time; on May 18, 1886, for the eighth; and on June 21, 1886, for the ninth time, the three cases being entirely successful. By these nine operations six women and nine children were saved.

In a tenth case Prof. Chiara made trial of the method of Sänger, by which Dr. Leopold, of Dresden, had saved eight of his nine cases, and all of the children; and was successful in saving mother and child. This favorable result will probably lead to the introduction, to some extent, of the Sänger method into Italy.

An additional Porro operation was performed in the Maternity of Florence by Dr. E. Fasola, assistant to Prof. Chiara, on April 19, 1886. Sänger's method was first tried, but was abandoned because of a severe uterine hemorrhage, and the method by amputation of the uterus substituted for it. It is generally believed that convalescence after the Sänger operation is more rapid than after the Porro operation, and this belief is strengthened by the experience of Prof. Chiara's Sänger case, in which the patient sat up for a short time on the tenth day.

SOCIETY PROCEEDINGS.

AMERICAN NEUROLOGICAL ASSOCIATION.

Annual Meeting held at Long Branch, July 21, 22, and 23, 1886.

(Specially reported for The Medical News.)

Wednesday, July 21.—Morning Session.

Dr. Burt G. Wilder, of Ithaca, N. Y., on retiring from the Chair, said that in view of the fact that he had delivered a somewhat extended inaugural address upon a general subject last year, he would confine his remarks to the brief discussion of what he believed to be a new fact, namely

THE ACCURATE COLLOCATION OF A SUTURE AND FISSURE IN THE HUMAN FŒTUS.

In three alcoholic fœtuses in the Cornell University, estimated to be from three to seven months advanced, the lambdoidal suture directly overlies a short but deep fissure, which has seldom been noticed and has been hitherto misinterpreted, and which may be called the

lambdoidal fissure. A photograph and drawing of one case were submitted; the fissure was very distinct and deep, but had no ental correlative in the cases examined. He remarked that Bischoff and Huxley had regarded the fissure itself as temporary in man, though persistent in apes.

Prof. Wilder believed the fissure to persist in man also, but to lose its relation with the suture in the last two months of fœtal life. He mentioned the probability that the coronal suture is similarly related with the precentral fissure, and closed his remarks with an enumeration of several questions that arise in connection with the subject, and with the suggestion as to making use of fœtal brains by careful exposure, preservation, photographing, etc.

PROF. WILDER then introduced to the Association Dr. Charles K. Mills, of Philadelphia, the President-elect.

DR. MILLS, on taking the Chair, made a few introductory remarks on the work of the Society, and on the proposed Congress of American Physicians and Surgeons. He then presented specimens and described the brains of a monomaniac, two murderers, an idiot, a negro, and a Chinaman; drawing attention to the

IMPORTANCE OF THE STUDY OF THE CEREBRAL CONVOLUTIONS

in these cases.

He congratulated the Association upon the large amount of published work which had been done by its members since the last annual meeting; instancing the fifth volume of Pepper's *American System of Practical Medicine*, out of the twenty-four contributors to which, more than one-half were members of the American Neurological Association. He urged the importance of individual effort toward increasing the membership of the Association, so that it would be in fact, as well as in name, the great national representative of those members of the medical profession who are interested in neurology and psychiatry, and the branches of science which are specially correlated to those branches.

He discussed at some length, and with approval, the project for the formation of a Congress of American Physicians and Surgeons; he pointed out that difficulties might arise in connection with the initiation and inauguration of the Congress. He spoke of danger apprehended by some, that the Congress, like another national medical body, might drift insensibly into the arena of medical politics, but believed, if wisdom prevailed during its development, that such might be avoided. He thought it would be better for the meetings of the Congress to be biennial, thus allowing the associations, as special organizations, to have entirely separate and independent meetings on alternate years. He also believed it desirable to have the meetings of the Congress held at a fixed location, and thought Washington the most desirable place, but held that this whole subject of the time and place of meeting was a matter of minor importance, and could be safely left to the judgment of the committee of conference.

He then exhibited the brain of Burk, a delusional monomaniac; that of Taylor, an alleged delusional lunatic, executed in Philadelphia; also that of a feeble-minded youth from the Pennsylvania Training Institute for Feeble-minded Children; as well as the brains of a negro and a Chinaman. The brain of the Chinaman was first exhibited at the Philadelphia Neurological Society, by Dr. A. J. Parker.

Dr. Mills stated that the Chinese brain was the first that had ever been described so far as he knew. In discussing the appearances presented by these specimens he gave what he regarded as the peculiarities of human brains of low type, and also the differences between the simian and human brain. He demonstrated that in the white adult brains presented, and also in others, of which descriptive notes were read, that there were easily recognized differences between these and those of individuals of higher grade. In all, asymmetry was distinctly atypical, both of lobes and gyral and fissural arrangement, he believed to exist in a marked degree between the two hemispheres.

In general terms, the white brains were found to approach more nearly in type the brains of the negro, ape, and fœtus than is ever the case in an ordinary adult white brain, even in individuals of moderate intelligence and intellectual power. He discussed the question, whether these specimens, some of them from men who had committed crimes of violence, who had taken the lives of their fellows, sustained the conclusions of Benedict and others: that the brains of criminals are absolutely distinctive; whether we had a criminal type of brain which could even be separated from the type which is found in forms of insanity. Such a generalization he regarded as too narrow.

In the brains presented, there were certain points of affinity and points of difference noted, from known conditions of higher human types; these were so great as to allow him to put them into a class together as representatives of brains of low type. He regarded the attempt, however, to construct a theory as to the anatomical basis of crime, in some respects unphilosophical; criminals and transgressors of the law being of the most diverse character. Dr. Mills criticised some of Benedict's conclusions, although he paid a tribute to his observations and regarded them as stimulating research to a wonderful degree. He thought it strange that so little research had been made in the morphology of the brain. Although we had a large negro population, but little had been done toward the mapping out of the negro brain. He remarked that no Indian brain had ever been described in detail, and thought some of our army surgeons on frontier posts, who had great facilities for such investigations, should undertake this interesting work. Dr. Mills also stated that he had looked in vain for a description of the conditions presented by the cerebral surface of an intellectual woman.

In conclusion, he remarked that although much study had been given to fœtal brains, no detailed investigations of the brains of infants, children, youths, and adults, arranged in series and accompanied by histories, etc., had ever been made; which he considered a highly important and valuable method of study.

DR. WILDER remarked that the subject was worthy the importance which the President had assigned to it, and he was afraid there were a large number of physicians and surgeons who were not as familiar with the

brain as they ought to be, and he considered it the highest compliment the President could pay to the Association in speaking in the straightforward manner he had assumed in his paper in relation to the anatomy of the brain.

He would have liked to examine the brain of the Chinaman more thoroughly in order to confirm some of Dr. Mills's statements. In the negro brain he had called attention to the exposure of the insula; he had one specimen where it was still more exposed and in the specimen he spoke of the brain was hardened in the skull so that there was no chance of undue pressure. He noticed that the Chinaman's insula was abnormally covered, but he thought it would not do to credit the Chinaman with it, as he noticed the brain had been flattened upon one side and the first temporal convolution had been pushed over the insula. He also agreed with the President in his remarks upon Benedict's generalization. He thought, however, they merited careful scrutiny.

With regard to the confluence of the Rolandic fissure and the Sylvian, he remarked that he should hesitate to say anything, but in some twenty or thirty brains that he had examined he had never seen the confluence of central and Sylvian.

He thought that it would be a difficult matter for him to find an average brain, and he suspected it was the same with a large number of others; he thought the brains that were studied were more or less peculiar, giving as an instance, that some years ago he secured six human brains for his students to dissect, but upon examination each of them had some peculiarities, and he concluded they were too valuable for ordinary dissecting.

He then asked the President, supposing he had not known this to be a Chinese brain before him, whether he would have felt disposed to note its peculiarities, and further if there was anything that would lead him to think it belonged to a different race from our own.

Dr. L. C. Gray, of Brooklyn, did not think there was any disagreement among neurologists as to the one-sided manner in which Benedict's researches were conducted. He thought it was unfair in Dr. Wilder to criticise any one point in a paper which contained so many individual peculiarities, until after a careful examination of the specimen. He thought that until some one has determined the limitation of the various convolutions in the human brain it would be difficult to set the line.

There were two points, he said, which had attracted his special attention, for in two negro brains which he had carefully studied, there was some uncovering of the fissure of Sylvius; but he had never seen the fusion of the fissure of Rolondo with the fissure of Sylvius.

Dr. Dercum, of Philadelphia, remarked that some months ago he had exhibited a brain from an epileptic female; the island of Riel was covered on both sides, but on one side the fissure of Rolando was confluent with the fissure of Sylvius.

He also remarked that Dr. Parker had described several fissures which had occurred in a negro brain on the mesial surface which were afterward ascribed to mechanical causes.

Mr. Joseph Jastrow, of Johns Hopkins University, by invitation of the President, stated that he had had twelve or fifteen brains before him for class demonstration, and after taking plaster impressions had taken composite photographs of them, hoping to establish, thereby, a standard brain.

Dr. Birdsall, of New York, thought that Benedict's theories were rather strained but may have stimulated further research. He also opposed the view that one peculiar type of brain must form that of a criminal. He thought the study of the cranium in different races would be of advantage, but that the study was still in its infancy as to relations between these peculiarities and their functions.

Dr. Sachs, of New York, remarked that he was naturally interested in the general anatomical bearings of the fissures. He thought we ought to distinguish between the primary and secondary development of the fissures. He remarked that it would have been important to know the conformation of the skull from which the brain of the Chinaman was removed, this he thought might prove an important factor.

Dr. Wilder remarked that he thought the discussion had been made in regard to the fissures which are considered as primary; he did not think much would be gained by speaking of the secondary fissures.

The President agreed with Dr. Wilder that it would be better to harden the brain in the skull. But in reference to the specimens he had shown, some of them were obtained under great difficulties, and he was glad enough to get the brains as they were. The fissure of Rolando, in one of the cases, was crossed by a convolution instead of being confluent. It is true, as Dr. Wilder has said, that many brains are peculiar, but perhaps it might be due to the reason that most brains secured are from those of low organization.

In regard to the Chinaman's brain, he would not have known that it belonged to *a different race;* there was a peculiarity of appearance, but he could not understand what it was. Dr. Parker noticed an unusual obliquity and shortness of the orbital surface. In regard to Benedict, he did not think we should be too severe in our criticisms, but he (Benedict) had a bad manner of generalizing.

In regard to Mr. Jastrow's remarks, he thought such experiments might be very interesting in studying the higher and lower types, but was not so certain of thus attaining a standard of the normal brain. He considered that Dr. Wilder had answered Dr. Sachs's remarks, and that he himself based his remarks upon the primary fissures principally.

An Executive Session was then held, and the following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Landon Carter Gray, M.D., of Brooklyn, N. Y.

Vice-President.—John Van Bibber, M.D., of Baltimore, Md.

Secretary and Treasurer.—G. M. Hammond, M.D., of New York.

Councillors.—Dr. B. Sachs, of New York; and Dr. Wharton Sinkler, of Philadelphia.

Dr. L. C. Gray, of Brooklyn, then read a paper on

LESION OF BOTH TEMPORAL LOBES, CAUSING ALMOST ABSOLUTE LOSS OF MEMORY OF EVENTS, WITHOUT WORD-DEAFNESS OR DEAFNESS.

Male, aged forty-three years, unmarried, with a probable history of specific disease. Patient was admitted to the Hospital for Nervous and Mental Disease in the early part of June, remaining there until the latter part of the month, when he was removed to the Morris Plains Asylum, where he died in October. During the whole of this time careful observation failed to detect any other symptom than that of absolute loss of memory of events, without word-deafness or deafness.

At the post-mortem there was found a lepto-meningitis of both the right and left temporal convolutions, which meningitis also extended around the fissure of Sylvius, involving the gyrus marginalis and the bases of the two ascending convolutions.

A number of letters of the patient were read, which showed this peculiar loss of memory and the preservation of his intellectual faculties in other respects.

Afternoon Session.

The President announced that the discussion upon Dr. Gray's paper was in order.

Dr. Wilder said that he had not quite understood the lesion Dr. Gray referred to in his paper.

Dr. Gray replied that meningitis was the only lesion in the case.

Dr. Zenner, of Cincinnati, asked to what extent the cortex was affected.

Dr. Gray replied that both temporal lobes were softened, and the layer of gray matter was much less than any other portion of the brain. No microscopical examination was made.

Dr. Zenner asked whether there was any confusion of speech.

Dr. Gray answered that he was told there was none at all, and he knew there was no evidence of it in the patient's letters.

Dr. Zenner remarked that he would not like to accept a case as refuting the ideas which have been generally accepted, that the temporal convolutions are the receptacles of speech, so to speak; in a case like this, where the softening was not marked as a meningitis, it does not necessarily rob the parts underneath of their function.

Dr. Gray stated that both temporal lobes were softened.

Dr. Zenner thought that could have occurred in the last few days of life. As regards the temporal convolutions being the seat of hearing, he thought that had been less definitely established; that it was only one of the organs in physiology, and that there was nothing which he knew of in pathology which would establish the temporal convolutions as the seat of hearing; but lesion of the temporal had been established to result in word-deafness.

Dr. V. P. Gibney, of New York, then read a paper on

PSEUDO-HYPERTROPHIC PARALYSIS.

He remarked that his motive for reading the paper was to record a case in order to supplement some microscopical specimens; the latter having been carefully prepared by Dr. Amidon. For many years he had been able to distinguish quite readily between a progressive muscular atrophy and a pseudo-hypertrophic paralysis; but what now surprised him was that the spinal cord had not been found to be diseased.

The case he reported came under his care in April, 1878; was under daily observation for one year, reporting from time to time afterward, and died December 30, 1885. Patient was a male, eight years of age, the loss of power dating from the second year of his life; but the mother felt no anxiety about the child's inability to walk, and did not seek medical aid until he was six years of age. The family are all decidedly neurotic, father, mother, and children, four or five in number, having all some peculiarity of speech. Three children have died of tubercular meningitis, so reported. One brother, two years younger than the subject of this history, is afflicted in the same manner, and his case is progressing the same way.

Dr. Amidon then presented for examination under the microscope some sections of the normal cord, and some specimens of the cord from the child whose history had just been given by Dr. Gibney; the only difference discernible being the change in the cells of the anterior horns, the contour of the cord being apparently intact.

Dr. Gibney asked whether there was any cord lesion in pseudo-hypertrophic muscular paralysis? whether the latter stages of this disease are distinct or whether they run one into the other?

Dr. G. W. Jacoby, of New York, remarked that the last time he had the pleasure of demonstrating a case, and in seventeen recorded cases, there was no change in the anterior cord; but, on the other hand, there was in the muscular tissue a shortening of the fibres, an increase of connective tissue, and an increase of fat. In some cases there was no reference made to the motor nerves in the muscles themselves. In others, where pieces of the muscular tissue had been removed and examined microscopically, atrophy of the terminal filaments of the motor nerves was found with other changes. He asked Dr. Amidon whether he paid any attention to that.

Dr. Amidon replied that Dr. Gibney had sent him a portion of the dorsal muscle for that purpose, but he had not yet examined it.

Dr. Sachs remarked that the subject of the paper was of practical interest at this time in neurology, as we had had an era in which diseases of the brain were discussed mostly; then there was an era of interest in the peripheral nerves. He thought that, in direct contradistinction to Charcot's school, we must take into consideration what Erb had done. He supposed that all knew that this condition is common in the young, but there is another form which is not, and which is called juvenile muscular atrophy; juvenile atrophy should probably be classed as a motor and spinal cord affection.

He thought there was one clinical point which would enable us to establish a differential diagnosis, and that would be by the electrical reaction. If the affection is peripheral only, the electrical reaction may slightly diminish or increase; but if central, it is not altered.

Dr. Zenner remarked that we know that a change in the muscular tissues produced by disease will pro-

duce a change in the ganglionic cells. He thought that where the disease had commenced in the muscles and nerves, there would be but slight change in the cord, perhaps only in the size, and no change otherwise in the intercellular tissue. It seemed as though the change there usually might be secondary, and that the extensive disease in the periphery is primary. He thought, however, that where there is extensive disease in the anterior portion of the cord the disease would be primary.

DR. GRAY remarked that it is true that peripheral lesions might cause central troubles probably travelling in along the nerve filaments, but there was no decided proof to that effect. In some cases secondary central disease occurred in animals where there was a neuritis produced by caustic, as also in human beings where caustic had been used upon the scrotum or testicles. One of these cases of peripheral disease of which he has known has been of a decided nature.

DR. MASSEY, of Philadelphia, thought that if there was no life in the muscles the cells would be affected.

DR. ZENNER explained that he had in view at the time he spoke the idea of serious injuries, as, for instance, the loss of an arm, after which atrophy had been found in the brain or cord.

DR. MILLS asked an opinion as to the difference between pseudo-hypertrophic paralysis and muscular atrophy; stating that one of the brains he exhibited in the morning was from a youth who presented congenitally these two diseases together. He was one of three brothers in all of whom these diseases were conjoined; some portions of the muscles were removed, and a report appeared some years ago of them by Dr. Curtin. His own convictions were that these two diseases were practically the same thing.

DR. LLOYD, of Philadelphia, stated that he had reported the case of a female in whom pseudo-hypertrophic paralysis and atrophy of the muscular tissues were combined; there was wasting of the calf muscles and also of those of the forearms, but there remained some faradic contractility, there was great muscular loss of power, she could hardly raise her head from the pillow. There were also marked changes in her joints, hardly any of the olecranon process was left, and the patellæ were only one-third of their normal size.

DR. GRAY remarked that he had a case in his wards who had been some six or seven years in dying. He has grown enormously fat for the reason that he had been kept quiet; he is helpless in his lower extremities and almost so in his upper ones but he takes an enormous amount of food. To look at him, one would suppose it to be a case of pseudo-hypertrophic muscular paralysis.

DR. G. M. HAMMOND, of New York, remarked that the destruction which occurred in the cells should not necessarily produce destruction of the spinal cord or atrophy, but if the disease extended from the muscles up the nerves it might do so.

DR. AMIDON said that he thought that in progressive muscular atrophy there would not be any caving in, so to speak, of the spinal cord.

DR. G. M. HAMMOND replied that a disease which commences in the spinal cord, might be extensive enough to produce caving in of the anterior horns, whereas in the specimens shown, the horns seemed to be in very good shape although the disease involved the cells.

DR. DERCUM, of Philadelphia, thought that point was well taken, for in some of his specimens there was absolutely no change in the contour of the horns; he considered that in this disease there was an atrophic condition of the cells more purely; there is not an active inflammation, but simply a shrinkage and gradual disappearance of the cells.

DR. GIBNEY in closing the discussion, thought the absence of the cells and slight loss of contour sufficient to account for the great muscular changes. But upon this point he was not satisfied, whether the loss of function and tone would not of itself account for the disappearance of the cells and their shrinkage.

DR. SARAH J. MCNUTT, of New York, then reported

A CASE OF AN INFANT WITH MULTIPLE TUMORS OF THE CEREBRUM, PROBABLY OF SPECIFIC ORIGIN.

The history of the child was given in detail. Both father and mother were intemperate, but no specific history could be obtained. The cause of its last sickness was owing to exposure, the child having suffered from gastro-intestinal trouble for some time. The temperature rose to 104°, the patient dying from paralysis of the heart.

The autopsy revealed in the lower lobe of the left lung a caseous mass the size of two peas, bronchial glands enlarged and cheesy, the liver was filled with small yellowish-gray masses, the spleen also being affected in the same manner. In various portions of the brain lymph and pus were found. The arteries appeared thickened, and in the left ascending frontal convolution just beneath the surface were two caseous nodules the size of small marbles, which could be shelled out as though encapsuled. Similar nodules were found in the parietal and occipital lobes.

Dr. McNutt then described very clearly the lesions which we are apt to find at the post-mortems upon children dying from transmitted syphilitic affections, concluding that in the treatment of these cases we must rely upon mercury promptly exhibited; inunctions she considered had given the best results, as the gummata in children apparently belonged to the secondary instead of the tertiary stage.

DR. WILDER asked what was the composition of the nodules.

DR. MCNUTT replied they were vascular and filled with large round cells.

DR. G. BETTON MASSEY then read a paper on *The Cause of Electrotonus, and the Normal Formula of Polar Reactions.*

THURSDAY, JULY 22.—MORNING SESSION.

DR. JACOBY read the report of the Committee on

ELECTRICAL DOSAGE.

It stated that special rules for the application of electricity do not exist. Individual differences between patients and diseases make this impossible.

DR. GRAY believed that some thought should be taken of the substance of which the electrodes were made, and also as to their coverings, as it would make a great difference in calculations; again, with what the sponges are wetted would make a difference; the temperature of the water must be taken into consideration, his rule being to

use water as hot as the patient can bear. The question of a galvanometer should also be considered.

Dr. Lloyd had felt a great deal of dissatisfaction in using electricity, especially in electro-gynecology, because he did not know what strength would produce certain effects; the area of surfaces making differences in the strength; the question to decide is how much current will produce a certain catalytic action; for instance, if you want to promote absorption of an inflammatory deposit in pelvic cellulitis or in stricture of the urethra, etc.

Dr. Weber stated that, so far as his experience went, an electrode, no matter of what it was composed, should be if possible square; he had discarded the use of oval ones. He thought the dosage of electricity an individual matter, and that no committee could lay down laws for its administration.

Dr. Massey thought there should be a standard milliampère meter. He thought it desirable that the Society should purchase a good meter for the use of instrument makers, to be kept in New York City. He thought the committee had devoted too much time to therapeutics. The points to be gained are determinations in milliampères; for instance, how many milliampères are required to produce a contraction in a certain muscle. He had recently made some preliminary experiments in that direction with the cathodic closure and the anodic closure; he thought a certain number of observations on normal muscles were necessary to determine the number of milliampères required to produce a contraction.

Dr. Jacoby, on behalf of the Committee, replied that he felt that the idea of the committee was lost to view. The committee was on dosage, not on galvanometers. The covering of electrodes did not enter into their consideration; Ohm's law covers that. If the resistance is increased, current strength must be increased. The reason why no particular galvanometer was recommended was because they did not care to recommend any particular instrument maker; all galvanometers have their objections; a selection must be left to individual choice. It would be a difficult matter to find a standard galvanometer; it would be difficult to find one remaining the same after a year; the best and most delicate he had ever used have changed; they are subject to magnetic influences. As regards the amount of current strength required to effect a certain result, if the committee were to inform the Association that a certain number of milliampères would cure a certain disease, it would be only individual experience. As regards the question of electrical dosage, he did not think absolutely normal muscles would give similar contractions. The recommendations of the committee are a plea for accuracy, to use the milliampère as has been done, but when you do describe the amount of current used, give the number of milliampères, and style of electrode used.

Dr. Amidon then read a letter from Dr. Fovel, of Zurich, and exhibited a photograph which he had sent of a

MICROCEPHALIC GIRL

who had three sisters also afflicted in the same manner, and who had since died. The parents were natural in appearance, and enjoyed good health.

Dr. Wilder stated that he wished to avail himself of this opportunity to retract what he had said yesterday in relation to the brain of the Chinaman, as he had since had an opportunity of carefully examining the same, and thought it the most remarkable brain he had ever examined, although there was nothing to point to its Mongolian origin. It presented some remarkable features, and in a great many ways pointed to our ape ancestry.

Dr. B. G. Wilder then presented some

NOTES ON THE BRAIN; AN ADDITIONAL CASE OF INDEPENDENCE OF THE PAR-OCCIPITAL FISSURE.

1. In his recent paper on the par-occipital fissure, he stated that among forty-three reliable specimens and figures accessible to him, the par-occipital was continuous with the parietal in twenty-one, and independent in twenty-two. The brain of a negro child at birth, lately prepared by him, had two fissures wholly independent on the right, and barely united by a shallow junction on the left side, the ental correlative of the occipital fissure in an early fœtus.

2. In a fœtus estimated to be about three months of age, opposite the occipital fissure there was a distinct ental ridge, so that the entire thickness of the wall was there folded. A similar ridge is figured by Tiedemann, but not named or described; that without further observations he could not determine as to whether it disappears in the adult or persists as a more or less distinct elevation, known as the bulbous cornu posterioris or eminenta splenalis. Even if transitory, it adds another to the list of fissures, including the calcarine, hippocampal, collateral, and Sylvian.

3. The fœtal extension of the proplexus is to the end of the post. cornu. This was the case in a fœtus estimated to be seven months old; the post-cornual extension is apparently in process of atrophy; there were indications of a like extension into the precornu. The extension might be expected in view of the great volume of the plexus at a still earlier stage.

4. Points illustrated by the transection of the fœtal brain. Six points of morphological interest were noted, most of them indicating that the thalami increase in width as development proceeds, so that in the adult human brain they form, or seem to form, part of the floor of the procœles or lateral ventricles, which is not the case in other mammals, excepting, perhaps, the primates.

Dr. Mills then presented the brain of a baboon and of a negro, sent by Dr. Formad, of Philadelphia, but time was not afforded for a careful examination.

Dr. Leonard G. Weber, of New York, then read a paper

ON SOME AFFECTIONS OF THE NERVOUS SYSTEM ASSOCIATED WITH TUBERCULOSIS.

He remarked that in phthisis there is a condition of the mind in which cheerfulness predominates, but there is one, also, in which the most gloomy thoughts are indulged in, frequently ending in insanity, and it was of this latter that he wished to speak. He illustrated his remarks with clear and detailed histories of two cases. He thought that the indicated treatment partook somewhat of Dr. Mitchell's plan of treatment; but in these cases one difficulty would arise, which is to make them rest, as he thought it would be an extremely difficult matter to confine such patients to bed. He thought that

in those cases where mental aberration occurs, it is desirable to examine the lungs, as often the mental symptoms appear long before any positive diagnosis of phthisis can be made.

Dr. Gray remarked that these cases have puzzled him sometimes, so much so that he has sent his patients to a specialist in auscultation for an examination of the lungs. He thinks there is such a thing as tuberculous poison in the blood long before it produces organic changes. A case was quoted by him in which the mental symptoms predominated, and a consultation was called as to what really was the trouble. The patient dying, an autopsy was made, and evidences of tuberculosis discovered. He thought Dr. Weber had looked at the prognosis of these cases in a rather too despondent manner, as he knows of several cases which have recovered and enjoy excellent health. As to treatment, he agreed with Dr. Weber, and the point is to secure absolute restriction of all expenditure of energy, giving them the largest quantity of food they can take.

Dr. Weber replied that he was glad to hear hygienic measures emphasized, and also the great point of diet discussed; in Germany this is very fully realized, and he has himself, while visiting there, seen it carried out with excellent results.

Dr. Van Bibber, of Baltimore, stated that he is in the habit of seeing a great many cases of melancholia, and that he makes a custom of always examining the lungs.

Dr. Parsons, of Sing Sing, New York, stated that he has had charge of a large number of cases of melancholia, and had noticed the frequency with which phthisis is associated with it; he has observed that frequently the disease of the lungs will run into the second, and even the third stage, without objective symptoms.

Afternoon Session.

A DECEREBRIZED FROG.

Dr. Wilder exhibited a frog which he had decerebrized more than seven months ago. The wound healed perfectly, and the animal has enjoyed perfect health ever since; the operation was performed on December 9, 1885. A minnow or piece of fish is given to him twice a week, but it requires two persons to feed him, as one has to open his mouth and the other puts the food in, and here a curious phenomenon presents itself—if a piece of the minnow's tail projects from his mouth, the frog, while making an effort to swallow the fish, will, with his fore feet, endeavor to pull the fish out of his mouth. The movements of the frog also are superinduced, for after remaining in one position for some time, he will slightly change his position. If placed upon a convex surface and this be slightly revolved, he will endeavor to balance himself. Dr. Wilder sometimes, while carefully observing him, would notice that he would wink with only one eye, but when irritated he would wink both eyes. He also wondered whether the animal ever slept, as on the least jar, when apparently asleep, he would instantly open both eyes. (The frog was then fed before the meeting, and exhibited the phenomena described.) Dr. Wilder remarked that he would like to know if a frog under these conditions could be hypnotized. Just before coming into the meeting, while removing the frog from his box, one of his hind legs was accidently broken, but it does not appear to cause any inconvenience, and apparently no pain is felt. This frog also can be laid upon its back, and will remain there without the aid of mesmerism. The question also occurred to him whether this frog was capable of procreating his species.

Dr. Gray asked if he had ever hypnotized this frog.

Dr. Wilder replied that he had not.

Dr. Mills thought it would not have that part of the brain requisite for hypnotization.

Dr. Sachs stated that he was in Goltz's laboratory for some time and saw frequent exhibitions of frogs, but nothing was removed, the parts were simply severed. He thought Dr. Wilder's method more thorough, and was surprised to see the frog live so long. He then asked Dr. Wilder if he had ever put a block of wood in front of the frog and then irritated it, to see if it would jump over it or avoid the obstacle.

Dr. Wilder replied he had not.

Mr. Jastrow, of the Johns Hopkins University, stated that he had a series of frogs at one time: 1, normal; 2, the same as this one; 3, the optic lobes were also removed; 4, everything removed. He had found that the more brain tissue was removed the more readily would the frog remain upon its back. These frogs could also be etherized.

Dr. Wilder remarked that where the parts were severed subcutaneously there might be a question whether union did not occur.

Dr. Zenner, of Cincinnati, stated that in the hands of some experimenters there had never been reproduction in the cord, but he did not know how it was in the brain.

Dr. Gray suggested applying a little acetic acid to one of the frog's legs, to see if he would try to brush it away.

Dr. Wilder replied that he had not neglected to do so, and with the usual result.

Mr. Jastrow said that he found a frog that had lost one leg, so he applied a little acid to its body. First the animal tried to brush it off with the sound leg, and afterward with the stump of the other.

Dr. C. L. Dana, of New York, read a paper on

PSEUDO-TABES FROM ARSENICAL POISONING.

The object of his paper was to report two somewhat unique cases of arsenical paralysis, presenting the symptoms of tabes dorsalis; next to show that arsenical paralyses, like those from diphtheritic poisoning and alcohol, present two types, one of which might be called the mixed or ordinary form, and the other the ataxic form; and to show also, if possible, that the ordinary teachings that arsenical paralysis is due to a diffuse myelitis is not correct, and that these paralyses are really the result of a multiple neuritis. The conclusions arrived at were: 1. That a disease resembling locomotor ataxia may be caused by arsenic given medicinally, absorbed from wall papers, or taken in a single large dose. 2. That arsenical paralysis of this type and arsenical paralysis of other types are not due to a diffuse myelitis, as has been taught, but to a multiple neuritis. 3. That arsenical paralyses, like those from diphtheria, alcohol, and probably other infections and poisons, are of two types: *a*. The ordinary mixed, motor, and sen-

sory paralysis; *b*. the pseudo-tabetic form, in which there is no pronounced motor paralysis, but marked sensory troubles, especially ataxia.

DR. MILLS said that the subject of arsenical paralysis was one in which he was especially interested. The case which Dr. Dana mentioned, and which he had reported, was one of poisoning from Paris green, He had reported a series of cases. He thought that in these cases of metallic poisoning the true way to look at it was, not to regard it as a myelitis, neuritis, or myositis, but to regard it as a protoplasmic poisoning; that the poison, as the causative agent, affected the nervous protoplasm in varying degrees, according to circumstances; and, although Dr. Dana had asserted his reasons for regarding this disease as a neuritis, he regarded it as more extended. In the case just mentioned, other members of the family partook of the poison. One died with symptoms of encephalitis; one or two came near being permanently paralyzed; and others remained with symptoms of neuritis. This, he thought, indicated that a broader and better generalization should be made.

DR. SINKLER stated that he could recall some points in the case Dr. Mills mentioned. There was atrophy of the muscles of the upper extremities, atony of the bladder, marked reaction of degeneration, but he suffered no pain.

DR. MILLS thought the patient had suffered considerable pain, and that anodynes were used.

DR. JACOBY stated that he reported a case of lead poisoning in which the diagnosis was very difficult indeed. The diagnosis was pseudo tabes due to lead poisoning. He expressed the opinion that the ataxia was due to a lesion in the cord, but now desired to correct himself; if he had that case here, he would say it was multiple neuritis due to lead poisoning. The patient is entirely well now, he stated, with absolute return of the patellar-tendon reflexes.

DR. SACHS remarked that in speaking of these cases we called them arsenical and lead cases as though the symptoms were similar; these poisons have also been compared to the poisoning in diphtheria. Now we know that in infections the poison spreads to the most distant parts of the body: why should it not in these cases be peripheral as well as central?

DR. MILLS thought arsenical poisoning could produce a neuritis, myelitis, or cerebritis, or all of these together.

DR. DANA, in closing the discussion, stated that perhaps he had put his cases rather stronger than he intended, but the ordinary teachings are that arsenical poisoning produces a myelitis. The main point he desired to bring out was that there is a form of the disease resembling locomotor ataxia; he thought this should be known. Again, he wished to show that arsenical poisoning can bring about a multiple neuritis.

DR. SINKLER read a paper on

THE TREATMENT OF FACIAL SPASM.

He entered at length into the results which had been secured by others in these cases, quoting an interesting case that had came under his observation, in which the biceps of the right arm was affected. All the teeth upon the right side of the mouth were removed, but no relief resulted. Gelsemium, cannabis-indica, quinine, eserine, nitro-glycerine, and electricity were used, but without any marked result; in fact, the pain now extended to the right thigh and leg. The operation of stretching the facial nerve was decided upon after consultation. From the date of the operation up to the present time, there had been no spasm. The force used in the stretching of the nerve was estimated to be about twenty-five pounds. He had seen the patient some four weeks after the operation; the right side of the face was palsied; she could not shut the right eye, and the corner of the mouth hung down; but the patient assured him she was willing to remain that way rather than return to the former terrible twitching. He thought in this case the disease was of peripheral origin, and that in these cases, after therapeutic measures have failed to relieve, the operation of stretching should be performed without any unnecessary delay.

DR. MASSEY remarked that he saw a case a few days since which had been brought to him a year ago; at that time he applied the galvanic current, and during the following year the patient had been entirely free from pain.

DR. DANA thought that statistics were rather fallacious, also that some cases might get well with a slight operation, or perhaps none at all. It must be taken into account that the case mentioned by Dr. Sinker had only been operated upon four months ago.

DR. E. D. FISHER, of New York, made some

REMARKS ON EPILEPSY,

enumerating the various phenomena occurring during convulsions, relying chiefly upon the use of the bromides for the relief and cure of the disease.

DR. SACHS, of New York, read a paper entitled

INTRACEREBRAL HEMORRHAGE IN THE YOUNG.

After referring to the increased attention neurologists were paying to the cerebral accidents of children, the writer recorded his conviction that intracerebral hemorrhage is more frequent in children than is generally supposed, and that many cases of this sort are classified under the head of meningeal hemorrhage. Dr. Sachs then reported two cases of intracerebral hemorrhage; one in a boy two and a half years of age, and the other in a young man of nineteen years. The first case was given in full, in order to place the diagnosis upon a firm basis. The child had typical right hemiplegia with aphasia, without coma convulsions at the time of onset. The onset was slow, aphasia setting in first, paralysis of the arm and leg some hours later. The recovery was typical of that which takes place in many cases of adult hemiplegia from apoplexy.

The writer gave the reasons why he held that in this case the apoplectic attack was due to hemorrhage rather than to embolism or thrombosis. As regards the differential diagnosis between meningeal and intracerebral hemorrhage, the lack of convulsions seems to be of unusual significance. In meningeal hemorrhage convulsions are invariably present, and their absence might argue, other things being equal, in favor of intracerebral hemorrhage. In the second case the young man had had two apoplectic attacks exactly one year apart. The histories of these attacks were very similar to the one given in the first case. In the first mild attack all symptoms developed and receded typi-

cally; in the second attack the onset was slow, there was coma lasting for over eighteen hours, and recovery is not yet complete, contraction having set in in the affected arm. No convulsions at any time. There was no specific history.

Using these two cases as a basis, the author of the paper entered upon a discussion of the changes in the walls of the cerebral arteries, permitting an effusion of blood into the brain substance. Autopsies on this condition are very scarce, but there is good reason for supposing (reference was made to some recently reported cases of Dr. Osler) that miliary aneurisms occur in young children, and that fatty degeneration of the cerebral arteries, permitting transudation of blood through the vessel-walls (Recklinghausen), is a not infrequent condition.

Discussion was invited on the following points:

1. Frequency of intracerebral as compared with meningeal hemorrhage in young persons not the subject of specific disease.

2. The value of convulsions as a factor in differential diagnosis.

3. Pathological changes in the walls of the cerebral arteries in the young.

Dr. Mills thought that intracranial hemorrhage occurs in the young more frequently than is imagined. He had made three autopsies in children from the same family, dying within a few days after birth. He found extensive meningeal hemorrhage in one case.

Dr. Lloyd then reported two cases occurring in young men, one eighteen years of age and the other younger. In one case it followed close upon an attack of diphtheria. In the other, the patient complained of not feeling well in the morning, and was compelled to go back to his bed. When Dr. Lloyd saw him he had passed into coma, with convulsions on the right side of the body. The patient was a confirmed inebriate. When first seen, coma and convulsions had set in, waves of spasm sweeping over the paralyzed side; there was also extreme lateral deviation of the eyes; right facial paralysis, face being drawn to the left side. He was a little puzzled about the case, as he did not expect to find a confirmed drunkard at the age of eighteen years. The boy died in a few hours, and the case had to be handed to the coroner. At the autopsy there was absolutely nothing found which would account for the conditions mentioned.

Dr. Zenner thought that in these cases it was difficult to tell, except by the autopsy, whether it is hemorrhage, thrombosis, or embolism; he considered that mere symptomatology is not sufficient in these cases for a diagnosis to be based on.

Dr. McNutt spoke of a case in which there were convulsive movements on one side of the body, and also of the face. At the post-mortem the brain was examined very carefully, but there was simply œdema of the brain; there was no hemorrhage on either side of the brain.

Dr. Amidon thought the lesion might occur in the circulatory apparatus, more especially the arteries. The most natural thing to look for, he thought, would be miliary aneurism, as remarked by Dr. Sachs, although he was inclined to think that was a disease of adult life. He had seen pathological specimens where the aorta was narrowed, the patients dying very suddenly from intercerebral hemorrhage. Barié has reported twenty-seven cases in which he states that the disease is almost always below the origin of the left subclavian artery; some of the patients previously suffered from vicarious menstruation or epistaxis.

Dr. Sachs called attention to the fact in regard to prognosis; he thought it made a great difference whether the child suffered from convulsions or not.

Dr. Zenner, of Cincinnati, presented a case of

AUCTIONEERS' CRAMP,

remarking that it came under that large group of cases termed professional neuroses, which generally affected the muscles of the extremities; but in this case the muscles of the face only were involved, mainly, if not entirely, those of articulation; and, so far as he knew, nothing similar had been reported, and therefore he thought it of great interest to the profession. He then gave the following history:

Patient a male, forty-five years of age, of good family history, had always enjoyed excellent health, following the occupation of an auctioneer. In March, 1885, was confined to his house for a month with an ulcer upon one of his legs. During that time he enjoyed good health, with that exception. He had been an exceptionally busy man, calling sales from morning until night, often refusing to leave the sale to obtain his lunch. After recovering from the ulcer and resuming his calling, he noticed, at the first sale which he cried, that he had some difficulty in his articulation, but it was not such as to cause him to desist from speaking. After three or four successive sales, during which time the difficulty kept increasing, he was compelled to abandon his business entirely. He now began to notice occasional slight difficulty of articulation in ordinary conversation, and also some subjective symptoms, consisting of a sense of fatigue of the muscles upon the left side of the mouth after talking, a sense of throbbing, and a dragging sensation at the left corner of the mouth. Dr. Zenner saw him about a month after these symptoms were first felt. At that time there was considerable general nervousness shown; further than this there has been no symptoms of disease, his general health being excellent. His weight is about the same, appetite fair, and sleeps well; general motility, on application of electricity, normal, as are also the tendo-reflexes.

He then presented the patient and drew attention to the fact that when the face was in a state of rest there was a certain increase of depth of the nasal fold, and a drawing-in of the left corner of the mouth which was due to a tonic spasm; the patient also felt a certain sense of pressure there, as though the cheek were pressed against the teeth. In ordinary conversation the contractions of the muscles are scarcely visible—in fact, some of his acquaintances have not noticed anything abnormal. He then requested the patient to call five rapidly as in calling a sale; on the rapid repetition of the word the contraction of the muscles upon the left side of the face was very marked, these being tense like a rigid band, while the right corner of the mouth was drawn upward, making it almost appear as though the contraction of the muscles was upon the right side of the face, while the left, to an ordinary observer, would appear almost normal; the patient also complained of a sense of very painful

fatigue on left side of face. The orbicularis oris in this case seemed to be the muscle principally involved, but other muscles were somewhat affected. He also stated that the patient himself discovered that by putting the end of a pencil under the lip and pushing it upward to relieve the tension, he could articulate much better (this effect was proved by the patient before the meeting). In this case he applied electricity, massage, and manipulation, the muscles responding to the current as promptly upon one side as the other. But this treatment had effected no very satisfactory results as yet.

Dr. Wilder remarked, that from where he was sitting, the difficulty seemed to be upon the right side of the face.

Dr. Jacoby stated that the same idea had occurred to him.

Dr. Van Bibber asked whether the patient had ever had any previous affections of the face or ears.

Dr. Zenner replied that he had not, and that the first thing the patient noticed was a slight heavy aching feeling in the left corner of the mouth, which had gradually increased. He thought that the muscles of the affected side being brought so constantly into action by one continual effort might account for the condition of subjective symptoms presented. Poore, in his analysis of seventy-five cases of writer's cramp, speaks of the neurosis being due to a persistent activity of certain muscles where the act of prehension is brought into play, and somewhat resembles this case in requiring an effort differing from ordinary conversation. The patient himself has never accepted the fact that his calling of sales has produced his difficulty, but rather attributes it to having taken cold while confined to his house for that month, as he was in the habit of sitting by an open window. Dr. Zenner did not dispute that there might be some other element involved. He concluded that although he had administered the iodides, electricity, etc., he thought that if these were pushed a little further, together with more thorough application of massage and electricity, and no better results secured, it would be advisable to resort to stretching of the facial nerves of the left side.

Dr. Jacoby asked how drinking affected the patient.

Dr. Zenner replied there was no contraction unless an effort was required.

Dr. Jacoby asked whether there was any specific history.

Dr. Zenner replied there was none, so far as he had been able to learn.

Dr. L. C. Gray inquired whether he had been examined with the ophthalmoscope.

Dr. Zenner stated that he had sent him to a specialist for that purpose, and there was nothing abnormal in that respect.

Dr. Gray then asked whether, on examining him with galvanism, any difference was observed in the contraction of the muscles.

Dr. Zenner replied not in the orbicular oris, to which he had specially directed his attention.

Dr. Lloyd asked whether the patient suffered from vertigo.

Dr. Zenner replied he did not.

The President remarked that the case was one of extreme interest, and that he was inclined to regard it as a professional neurosis. He cited a case in which he had been called in consultation by Dr. C. H. Turnbull, of Philadelphia, to see an actor who was compelled, in his part, to distort his face to a peculiar expression requiring great effort; the result of this effort was followed by double vision, which at last compelled him to seek Dr. Turnbull's advice. He was then suffering from paralysis of one of the recti muscles. There was one peculiarity, and that was that with an increased voluntary effort the patient could draw the affected eye into its normal position.

Dr. Mills thought cerebral exhaustion was a factor in this case, and stated that although this condition lasted some time, the patient had almost recovered. He also thought this patient of Dr. Zenner presented some of the appearances of secondary contracture, the case presenting symptoms which he had observed in cases of peripheral neuritis, and which had spread and involved a large part of the muscles of the face. He thought the line of treatment suggested by Dr. Zenner very good: rest to the parts, and an endeavor to restore nutrition, being most desirable. He also thought that if recovery was delayed under these conditions, stretching of the nerve should not be postponed too long, that it was distinctly indicated when other means failed.

Dr. Gray remarked that it would require a most careful examination by the electric current to form a differential diagnosis, but he had thought there was a difference of power of the two sides while making his examination, and that the patient was paralyzed on one side of his face, and that there was a difference in the closing of the eyes, also while closing his lips upon his fingers it occurred to him that there was loss of power upon the left side.

Dr. Gray then asked whether his tactile sense was perfect.

Dr. Zenner replied that it was.

Dr. Weber remarked that the case did not seem to start as a neurosis, and that the contraction of the muscles seemed to be more clonic than tonic; this, to to his mind, was more secondary, as this is often found in post-hemiplegic conditions. He thought, as had been remarked, that galvanism was indicated.

Dr. Zenner, in closing the discussion, stated that he would not deny that there was neuritis present, though there was no direct evidence of it. He had not pretended to say what is the exact seat or nature of the disease in the patient. In most cases of professional neuroses the nature of the disease is altogether obscure, probably there may be a different pathological basis in different cases. In a number of cases of writer's cramp neuritis appeared to be the cause. But that his own case was properly classified with professional neuroses, was based upon the features peculiar to almost all such cases: first, that it seemed to have as its cause the excessive use of the affected muscles; secondly, that the peculiar symptoms were brought out in each instance only when those muscles were brought into play by a voluntary act.

When he attempts to repeat a word rapidly there is a rigid contraction of the muscles at the left angle of the mouth, pressing it firmly against the teeth, and at the same time some of the muscles on the right side contract, though much less forcibly, pulling the mouth toward the right side. The elevator muscles of the left upper lip alone take no part in the spasm, so that it appears as if there were paralysis of that side of the face,

and the face was merely drawn to the other side. But the patient revealed that there was no paralysis of these muscles by exposing the upper and lower teeth, by moving the mouth to one side and the other, all of which was as well done on the left side as right. The strength of the elevator muscles of the left upper lip was further shown by the patient's holding the lip elevated while the examiner made forcible and persistent effort to pull it down.

The speaker had repeatedly examined the patient for paresis of some of the muscles, which is often the basis of spasms of various kinds, in cases of writer's cramp as well as other kinds of spasm, but has never been able to detect any marked weakness of any of the muscles.

Friday, July 23.—Morning Session.

Dr. Wilder exhibited a beautiful specimen of

A median section of the head of a murderer injected with alcohol,

and remarked that the features of the brain which was thus hardened and exposed *in situ* are to be discussed at a future meeting, in comparison with the brain of another murderer. The specimen was an illustration of the value of the method of continuous arterial injection with alcohol which has been applied to other heads, to brains, and to entire bodies, in the anatomical laboratory of the Cornell University. The main features of the method are: *a*. Reception of the head within twenty-four hours after death. *b*. Preliminary washing out of the vessels with chloral, to which perhaps weak alcohol might be preferable. *c*. Continuous injection of alcohol for a week. *d*. Continuity secured by a pressure of eighty millimetres of mercury, which was afterwards reduced to forty millimetres, when the flow became somewhat free. *e*. Gradual increase of the strength of the alcohol from sixty-five to ninety per cent. *f*. Maintenance of a low temperature, 8° to 11° C. *g*. Accurate division of the head with a fine saw acting in a mitre box. *h*. The small cost; the injected alcohol represented forty-one and a half litres and ninety-five per cent., but about two-thirds was regained, so at three dollars per gallon it would not cost eleven dollars, and at seventy-five cents (free of tax) only three dollars.

Dr. Mills stated that he did not, ordinarily, care to use alcohol for the preservation of specimens for gross study, but used in this way it might be different in its results.

Dr. Amidon remarked that a little corrosive sublimate put in the alcohol might secure still better effects.

Dr. Mills asked whether there would not be great difficulty with a brain preserved in this manner in separating the pia mater from the surface of the brain; whether the brain would not be considerably torn. The old method was to put the brain in a solution of chloride of zinc; the membranes could then be readily stripped off in a few days, and weak alcohol afterwards used.

Dr. Wilder replied that the question of Guiteau's brain could have been more fully discussed if it had been hardened in the skull; and he felt this very desirable in order to preserve its shape. He hoped to combine with this process the preservation of the brain. so that the gyra and fissures could be studied. He has been preparing brains for the museum of the Cornell University for some years, and has found alcohol to answer all requirements for the purpose of microscopical examinations. He insisted also that the brain should be in the dura—in its own bag, so to speak; then hanging the brain over a pail by the dura, injection with alcohol is commenced, the brain then immediately fills the dura as though it were in the skull, and no pressure upon any one point exists.

Dr. Jas. H. Lloyd, of Philadelphia, read a paper on

Moral insanity: a plea for a more exact cerebral pathology.

It was devoted to a criticism of those who—in the manner referred to by Locke in his "Essay Concerning Human Understanding"—confuse in their psychology the *power* with the *agent*. They personify the "faculties," and regard them as distinct agents, each with its own province and powers. This method is inherited from the philosophers, and was shown to have produced the artificial distinctions between "mind" and "brain," and to have worked confusion, especially in the Scotch school, in the use of such terms as "consciousness" and "idea." The alienists in their writings have not escaped these errors, and many of the artificial distinctions, classifications, and symptomatologies which abound in the books are distinctly traceable to them. Brief allusion was made to the definitions and tests which have been promulgated in the courts, and are found in the writings of Coke, Hale, Blackstone, Shelford, and Chitty. To these we are indebted for such distinctions as "civil and criminal," and "partial and total" insanity. Also to such tests as *delusion* and *knowledge of right and wrong*. These were all shown to be more or less artificial and incomplete from the very standpoint of Locke's criticism—*i. e.*, they ignore the individuality of the brain as one acting *substance*, and grant to the faculties, or several activities, of the cerebral organ each its own autonomy, and its own disorders and diseases. They erect one symptom into a whole disease, and insist upon the presence or absence of this as a test.

The writer proceeded to an examination of the claims of so-called *moral* insanity, as presented by some of the most advanced medical psychologists. This claim proceeds upon just such an abstraction as the reader was cautioned to avoid. It presupposes a distinct moral faculty, which may remain undeveloped in a mind intellectually normal, or may become diseased without affecting the other faculties. This was almost the worst form of abstraction and personification that had appeared in psychology. It is impossible to conceive of a *moral* or *emotional* act of mind which does not include the so-called *intellectual* faculties. In fact, in these acts it is the cerebrum taking on only different (and rapidly changing) modes of action. To say that it is diseased in one of these modes and not in the other, is a sophism. It is more nearly correct to say that in an insane man it is the whole mental (cerebral) act—memory, judgment, emotion, and will—which is wrong, as these are all but *modes of action* of one diseased substance, the cerebrum. More careful analysis would prove this in the cases which are cited in the books as "moral imbeciles," and which include evidently such diverse types as hysteria, katatonia, paranoia, imbecility, melancholia, and even delusional insanity. The subject has importance because it is often relied upon to acquit a certain class

of lunatics in the courts, and almost invariably proves to be a broken reed to him who leans upon it. The paper closed with a reference to the labors of the experimental physiologists, especially Ferrier, who have demonstrated the localization of many sensory and motor areas. It is not possible for them to demonstrate the localization of "judgment" and "emotions." These are phases of all cerebration, and, as Ferrier distinctly states, exist both in the sensory and motor regions.

The President stated that he had great respect for the metaphysical and practical knowledge of Dr. Lloyd, but he must differ with him on some points; though, perhaps, it might be differences upon terms or expression rather than facts. He did not see what was to be gained by carrying out of the ideas as expressed by Dr. Lloyd in regard to nomenclature and classification. In using such terms as monomania, paranoia, and coming to kleptomania, or typhomania, and even some of those small forms of so-called phobias, we do it understanding what we are doing, but we do it as a matter of science and study. Again, Dr. Lloyd remarked we did not bring forth the cases to prove the propriety of the use of such terms. He thought the writer might not be thoroughly acquainted with all the cases produced in literature which led us to have a right to say that there are cases which deserve this designation of moral insanity. Men who have advocated the term moral insanity are perfectly well aware that in every case, unless it is where there exists general paralysis, physical and mental, there is also exhibited mental impairment. The cases to which should be applied this term, "moral insanity," are cases which have all through life exhibited a preponderance of moral defect, a decided evidence of moral impairment, though in many cases one may find but little intellectual impairment. He agreed with Dr. Lloyd that the term had been used indiscriminately, and had been made to cover cases of hysterical insanity, katatonia, etc. He thought that while paying tribute to Dr. Lloyd's scientific and and literary abilities, an acceptance of his ideas would rather retard than aid the advance of science in this direction.

Dr. Gray remarked that there are three classes of insanity, mania, melancholia, dementia; all other forms being simply forms or degrees of these. He did not see how we were to do away with the term, as it is an extremely difficult matter to draw the line sharply; but still we should know what it means and understand it.

Dr. Parsons thought the laity objected to it because it embraced so many forms of the disease, it may mean emotional or wicked insanity. But in speaking of a man as having a diseased liver, we do not mean to say that he is not sick. His views, he thought, had been well expressed by Drs. Gray and Mills.

Dr. Mills said he would like to ask a few questions: First, whether in discussing the question of insanity we have any right to use such terms as moral and immoral insanity. If so, in what sense should they be employed? Do not those who see cases of insanity frequently see those who present overwhelming predominance of moral or immoral phenomena? In a case, the trial of which lasted four weeks, the man being what we would term a delusional monomaniac, he plead his own case before the court, and the jury declared him sane. There was little or no immoral effect in this man's case; one could not use those terms.

Dr. Gray asked why we could not have localization in regard to the actions of the mind; if we can have mental symptoms by impairment of localized areas, why can we not have localized insanity by impairment of these areas?

Dr. Lloyd, in closing the discussion, remarked that he had in his paper already answered the questions on the subject of moral insanity; that it was something more than mere difference in terms. As to our courts, we should not despise them; they have a right to expect that a physician should express himself intelligently. In the case of a man killing his wife after years of happiness and affection on either side, he may say he killed her because he loved her; his brain is affected, his mind, his intellect is affected. It is, as was said in the paper, a mere word differentiation, it is not a differentiation of things. As to the subject of paranoia, it is a congenital defect of the mind, it comes from the mother's womb, it is hereditary.

Dr. Jacoby presented, for Dr. Rudisch,

A NEW PORTABLE BATTERY,

the chief point being that the cells containing the fluid can be left at home and the zincs and carbons replaced in the box. A current can be obtained from them after being once charged at the end of four weeks. Between the carbons and the zincs a piece of stout asbestos paper is fastened by means of a few thin rubber bands. The fluid used in the battery is composed as follows: sal ammoniac, one and a half pounds, add six pints of water. The asbestos paper retains in its pores a large amount of moisture, acting as a large voltaic pile.

A resolution was adopted approving of the proposed

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS,

and the following Committee of Conference were appointed: Drs. L. C. Gray, of Brooklyn; J. Van Bibber, of Baltimore; W. Sinkler, of Philadelphia; E. C. Seguin, of New York; and Philip Zenner, of Cincinnati.

Adjourned.

NEWS ITEMS.

Death of Prof. William Ripley Nichols.—Prof. William Ripley Nichols, a chemist well known in this country, died at Hamburg, Germany, on Wednesday, July 14th. He had been in poor health for the last four or five years, having been affected during that time by a peculiar disease of the lungs, which developed itself suddenly. He was Professor of General Chemistry in the Massachusetts Institute of Technology. He was one of the earliest graduates of the Institute, his class (that of 1869) being the second to leave its walls. He was the author and compiler of several admirable text-books. He was about forty years of age. As a chemist his work in water analysis was well known.

Death of Dr. Wilhelm Frobelius.—The death is announced, in the Russian papers, of Dr. Wilhelm Frobelius, formerly a great ophthalmic surgeon in St. Petersburg. When ophthalmoscopy was in its infancy, Dr. Frobelius wrote largely on the subject, and he was the first to perform iridectomy for glaucoma in St. Petersburg in 1857. He was appointed inspecting offi-

cer to the foundling institutions in 1864, and gathered under him a number of young subordinates of great ability and scientific attainments, who have rendered the greatest service to the important establishments committed to their charge; he obtained the appointment of a prosector, the first of these officers in the country. He also established, as early as 1868, an institution in St. Petersburg for calf lymph vaccination.

The New Iowa State Board of Medical Examiners met recently and adopted rules for granting certificates, and a schedule of minimum requirements of medical colleges to secure recognition, was adopted. A list of nearly three hundred medical schools was adopted to be recognized by the Board. Nearly one hundred colleges were refused recognition. Certificates will be refused upon failure to present a diploma from a recognized medical college, failure to submit the proper affidavits, or, upon examination, to answer correctly eighty per cent. of the interrogatories propounded. In all cases recommendation of good moral and professional standing must be given. The Board held meetings in other parts of the State, beginning at Dubuque, July 29, Mason City, Fort Dodge, Sioux City, and Council Bluffs, stopping two days only at each place, when examinations will be had and applications received for certificates, and diplomas verified. These meetings are held for the convenience of physicians in different parts of the State. All midwives in the State are required to conform to the same rule as physicians, and secure a certificate to practise.

Unwholesome Canned Peas.—The Health Board of Brooklyn has been looking into the healthfulness of French peas, and has condemned large quantities on account of injurious articles used in their preparation. The names of the brands which the Brooklyn authorities have decided to be unhealthy are the following; Henry Deler et Cie, Dandicolee et Gaudin, Bordeaux; J. Nouville, Bordeaux; Perry fils, A. Lazun, E. Estibal, Bordeaux; E. M. Daelzin, Bordeaux; D. M. Auzone, Bordeaux; L. Carpe et Cie, Lunéville; Soule et Prise, Bordeaux; F. Fitonaine, Bordeaux; John Moir & Son, London, Aberdeen, and Seville; Charles Julien, Paris; Barton fils, Fontaine Frères, Paris; G. Talbot, Bordeaux. These names are given, as it may be useful to know what particular brands are held to be unhealthful. Five hundred grocers in Brooklyn have been notified not to sell peas coming from these houses.

Congress of Naturalists in Berlin.—This year's assembly of naturalists and physicians in Berlin promises to be on a grand scale. It has been decided, says the Berlin correspondent of *The Lancet*, through the initiation of the German Colonial Association, to form a special section for Medical Geography, Climatology, and Hygiene, in which observations and personal experiences made in foreign countries, especially in the tropics, are to be discussed. The German Colonial Association has undertaken to make the necessary preparatory steps. Geheimer Medicinalrath Hirsch is the Chairman for the formation of such a section, the cooperation being secured of competent men, who, in the general interest, would be willing to assist personally at these discussions. The following are the subjects which will occupy the attention of the section: 1. Acclimatization in general: (*a*) The fitness for acclimatization of special races; (*b*) Hygiene of the white races in the tropics. 2. Education; capability of training the natives to work. 3. Sanitary and educational statistics in respect of German colonies and dominions under German protection. Professor Waldeyer, chief of the Anatomical Section, has proposed the appointment of a special session for discussing the subject of Gastrula of the Vertebrata, and offers to introduce the debate by a short report on the results of discoveries up to the present time. Professor Hartmann will conduct the investigation of the anatomico-zoötomical collections, for which the building of the old Exchange has been chosen.

Prehistoric Dentistry.—Dr. Marter, of Rome, has for some time past been devoting considerable time to examining the skulls in the various museums in Italy, and in Etruscan and Roman tombs, and he has given an account of his investigations in the *Independent Practitioner*. In the ruins of one of the Etruscan tombs, about the date 500 B.C., he found a partial denture. It was an arrangement for holding in position three upper artificial teeth by banding them to the adjoining natural teeth. These teeth were carved out of some large animal's tooth. Another denture found in an old Roman tomb consists of two natural teeth fastened by means of soft gold bands to the contiguous teeth. The most recently opened and oldest Etruscan tomb yet discovered in Italy was lately excavated at Capadimonti; this tomb belongs to the sixth century B.C., and amongst several articles of jewelry a denture, very similar to those above described, was found. Dr. Marter was unable to discover any stopped teeth, although many cases of caries and other dental diseases presented themselves. It is certain that dentistry must have been extensively practised in the early history of the world, and that gold must have been used largely; otherwise the early Greek or Roman legislators would not have mentioned the matter in the celebrated laws of the twelve tables. Law 5th, de Jure Sacrorum, is as follows: "Quoi auro dentes vincti sicut in cum ollo sepelire, se frande esto."

Trinitrine.—This term has been adopted on the Continent in prescribing nitro-glycerine, that nervous patients may not be alarmed by reading the latter word.

Lobelia Inflata: new Alkaloid.—Herr v. Rosen, of the University of Dorpat, finds two alkaloids in the lobelia inflata, one a liquid, lobeline, the other a crystalline solid. The latter was found to resemble apomorphia in its emetic characters.

Arsenic in Skin Diseases.—The Editor of the *Journal of Cutaneous and Venereal Diseases* is desirous of ascertaining to what extent arsenic is used by American physicians in the treatment of skin diseases, and also the results of their experience as to its therapeutical value.

Information upon the following points is requested of every physician who reads this:

Are you in the habit of employing arsenic, *generally*, in the treatment of skin diseases?

In what diseases of the skin have you found arsenci of superior value to other remedies?

What ill effects, if any, have you observed from its use?

What preparation of the drug do you prefer, and in what doses do you employ it?

Address, Editor of *Journal of Cutaneous and Venereal Diseases*, 66 West Fortieth Street, New York.

The British Medical Association will hold its fifty-fourth annual meeting at Brighton next week, under the presidency of Dr. Withers Moore, of Brighton. The Address in Medicine will be delivered by Dr. John S. Billings, U. S. A., and, by special arrangement, will appear in our columns of next week.

The Cholera in Japan.—Since the first appearance of the cholera in Japan this year, and up to June 20th, there have been 10,276 cases of the disease, 7803 of which have been fatal. The average death-rate per 100 has been 75.93. The total number of cholera cases which occurred throughout the country, from August 23d to November 30th, last year, was 11,927, of which 7152 proved fatal, the death-rate being 59.96.

Fancy-bred Rabies.—An English writer, Crawford, is authority for the statement that an American named Stephens, to test his theory that hydrophobia is fancy-bred in man, never loses a chance of getting bitten by a mad dog. He has been wounded by canine teeth forty-seven times, and a German named Fischer, who is his disciple, nineteen times. As there is certainly such a disease as simulated rabies, he advises some society for the diffusion of useful knowledge to scatter broadcast the small volume on "Le préjugé de la Rage," by Fangère Dubourg, and what was written on this subject by such lights of science as Bouley, Brechet, Tardieu, Majendie, Boudin, Vernois, Sausen, Renault, Donnat, Baron Portal, and Dupuy.

Illegal Practice of Medicine.—In Troy, New York, there would seem to be an admirable opportunity for the enforcement of the existing statutes against the illegal practice of medicine. A certain Mrs. Hoyt, of that city, some time ago obtained a diploma from an institution known as the "American Health College," of Cincinnati, claiming, it is said, to be incorporated under the laws of Ohio, which authorizes her to practise the "vitapathic system of medicine," whatever that may be. She states that she was graduated from the college after an attendance of *eight weeks* upon its course of study, and that she also has a certificate from the institution authorizing her to perform the functions of a minister of the Gospel. Acting upon the powers conferred by the latter, it is asserted that she has already officiated at two marriages; but to what extent she has inflicted the "vitapathic system of medicine" upon the community has not transpired.

NOTES AND QUERIES.

INTERNAL AND LOCAL MEDICATION IN THE TREATMENT OF HERPES ZOSTER.

During the past year and a half there have come to my notice, at various stages of the disease, a number of cases of herpes zoster, and as the following method of treatment has given very gratifying results, it occurred to me that it might be of interest to your readers. The treatment consists briefly in the administration of a blue pill (two or three grains) twice or three times during the day, and the local application of zinc ointment carbolized (two per cent.), the parts being also protected from irritation of the clothes and other external influences. In every case so treated the pain ceased and the eruption was controlled in the course of a day or two, or after the purgative effects of the drugs had disappeared, the vesicles drying up, leaving brownish crusts, the latter dropping off in the course of a few days. J. B. S.

THE HYPERÆMIA OF HOMATROPINE.

To the Editor of The Medical News,

Sir: In the issue of The Medical News of July 24, in speaking of homotropine hydrobromate, Dr Jackson says he believes the hyperæmia produced by this drug to be due to a specific influence of the drug on those vessels through which it makes its way to the general circulation, and that the same occurs after atropia. . . . To prevent the unpleasant irritation produced by homatropine, I have been using a few drops of a two or four per cent. solution of cocaine. It seems not only to prevent the conjunctival hyperæmia, but also to increase the action of the homatropine. In the hyperæmia produced by atropine, cocaine had no effect. In my experience atropine produces palpebral as well as ocular hyperæmia, and often facial erythema. When once these symptoms are produced, at any time afterward the smallest quantity of the drug is sufficient to excite another attack; with homatropine this is not the case. Very respectfully,

J. M. Ray.

Louisville, Ky., July 28, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM JULY 27 TO AUGUST 2, 1886.

Brown, Joseph B., *Colonel and Surgeon.*—Retired from active service, July 26, 1886.—*S. O. 171, A. G. O.*, July 26, 1886.

Bentley, Edwin, *Major and Surgeon.*—Ordered for duty as Post Surgeon, Fort Davis, Texas.—*S. O. 92, Department of Texas*, July 22, 1886.

Taylor, M. K., *Major and Surgeon.*—Granted leave of absence for one month, with permission to apply for one month's extension.—*S. O. 77, Department of Missouri*, July 24, 1886.

Girard, Joseph B., *Captain and Assistant Surgeon.*—Granted leave of absence for three months, with permission to go beyond seas.—*S. O. 170, A. G. O.*, July 24, 1886.

Robinson, Samuel Q., *Captain and Assistant Surgeon.*—Ordered for duty as Post Surgeon at Fort Brown, Texas.—*S. O. 92, Department of Texas*, July 22, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING JULY 31, 1886.

Long, W. H., *Surgeon.*—Granted leave of absence for fifteen days, July 30, 1886.

Sawtelle, A. W., *Surgeon.*—To proceed to Portland, Oregon, and Port Townsend, Washington Territory, as inspector, July 26, 1886.

Devan, S. C., *Passed Assistant Surgeon.*—Granted leave of absence for ten days, July 26, 1886.

Fattic, J. B., *Assistant Surgeon.*—Granted leave of absence for twenty-nine days, July 26, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING JULY 31, 1886.

Lumsden, G. P., *Passed Assistant Surgeon.*—To duty at Marine Barracks, Washington, for month of August.

Cordeiro, F. J. B., *Assistant Surgeon.*—Ordered to Receiving Ship "Minnesota."

The Medical News *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course, not necessarily for publication.

All communications relating to the editorial department of the News *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

MEDICINE IN THE UNITED STATES, AND ITS RELATIONS TO COÖPERATIVE INVESTIGATION.

The Annual Address in Medicine delivered before the British Medical Association, Wednesday, August 11, 1886.

BY JOHN S. BILLINGS, M.D., LL.D. EDIN.,
SURGEON U. S. A.

MR. PRESIDENT, AND GENTLEMEN OF THE BRITISH MEDICAL ASSOCIATION: You all know that the representative of the American medical profession first selected by your executive committee to deliver the Address in Medicine to-day, was the late Dr. Austin Flint, Sr., of New York, whose death last March is, therefore, a great and direct loss to you as well as to America. Every English physician knows Dr. Flint by reputation and through his writings; but only those few of you who were so fortunate as to know him personally, can fully appreciate the magnitude of the loss which the medical profession has sustained in his death.

This is not the time and place to attempt to pronounce a fitting eulogium upon him and his work, and I shall, therefore, only say that my deep personal sorrow for his removal is mingled with sympathy for the members of this Association, who have been thus deprived of the pleasure of hearing him state in person some of the results of his long and wide experience. The loss is not a total one, it is true, since he had, fortunately, completed his address on "The Medicine of the Future," which has been published, and has, no doubt, been read by all of you; but in this case the printed page is by no means a satisfactory substitute for the spoken word.

In accepting the request, with which I have been honored by your Council, that I should attempt to take his vacant place on this occasion, it is with a full understanding of my inability to fill it that I stand before you.

The request came at a time when I was hard pressed by official duties, and had neither leisure nor opportunity to undertake any special research; hence, to avoid violating one of my favorite Scotch maxims, viz., "That which you do not know, tell that not to any one," it was necessary to select some subject to which I had already given consideration, and which at the same time would probably be of interest to English physicians. Reflection on these restrictions soon brought the field of selection into narrow limits, almost into "a small intercept of space of one dimension," as a mathematician would say.

What is the significance of this invitation extended for the first time to a physician of another country, and that country the United States, to come to this annual gathering of the medical men of Great Britain and give the address in medicine?

Does it not mean recognition of the unity of medicine, of the utility of coöperation, of the fact that we have common interests, and that the time has come when it is desirable to hear from the outlying younger branch of the family with a view to mutual pleasure and profit in the future? So it seems to me; and I propose, therefore, to call your attention briefly to some points relating to the present condition and future prospects of medicine in the United States, and to the direction in which you may reasonably hope and expect from that country in the future the most useful coöperation in the improvement of medical science and art. I believe that these must be matters of interest to you, and that I can perhaps make clear certain peculiarities which do not seem to be as generally understood on this side of the Atlantic, as it is desirable that they should be, to insure sound judgment upon some of the results observed.

In the first place, permit me to call your attention to the fact that it is hardly possible to make any statements with regard to medicine in, or the medical profession of, the United States as a whole, which shall be definite and at the same time distinctive; that is, which will not apply almost equally well to medicine and the medical profession in other countries. This is due to the fact that there are great differences in the organization of the profession in different parts of America, so that what is true of one State would not be true of another; what is required as to fitness or qualification to practise in one place is not required in another; and the country covers so many parallels of latitude and meridians of longitude, making the conditions of life so diverse, and producing such differences in the prevailing diseases, that a man who is fairly qualified to practise in one section may be poorly fitted to treat the endemic diseases of another.

As in painting a picture, it is best to locate and define the shadows first, and deal with the lights afterward, let us begin by considering some of the things that American physicians complain about; in other words, some of their supposed grievances. One of these is that the profession is overcrowded; that there are too many doctors, both *in esse* and *in posse*, and that this is due to too low a standard of education, and to the want of legal restrictions as to the qualifications which shall give a man the right to practise. The feelings of some of our physicians on this subject are in full accord with those of the good old New England deacon who told the village scapegrace seeking admission, that "he thought the church was about full."

Now what is the number and distribution of medical men in America? Statistics gathered in 1883[1] showed that in the United States and Canada there were 90,410 persons calling themselves physicians, being in the proportion of 1 to every 600 of population. In Canada alone, there were 3487 physicians, or 1 to 1112 of population. If we take the figures of our last census, of 1880,

[1] Illinois State Board of Health Report, 1884.

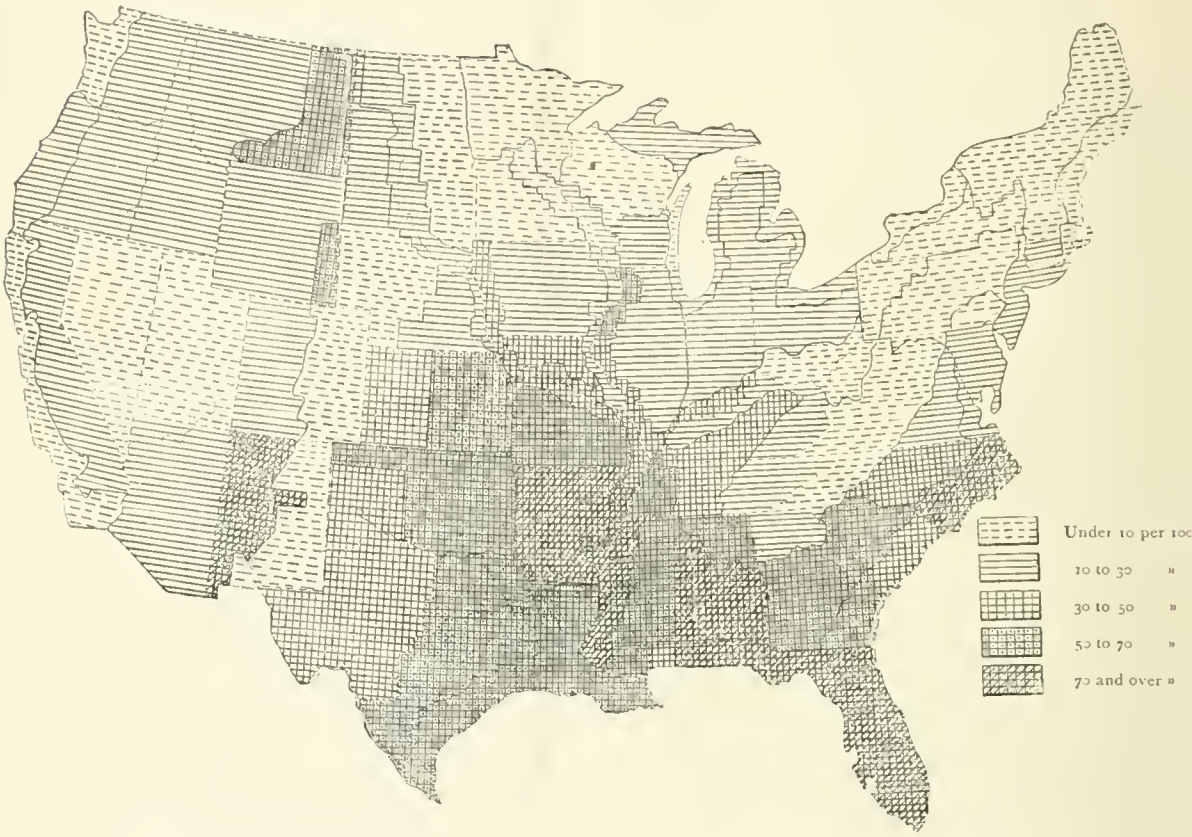
the proportion of physicians reported, is 1 to 589 of population, or 17 per 10,000. In England and Wales, by the census of 1881, the proportion of physicians is only 5 8 per 10,000, but these figures are not properly comparable with those of the United States, because they do not include unregistered persons. If the same classes were included that are counted in the United States report, I presume that the proportion would be about 9 per 10,000, or a little more than half that in the United States.

In the United States the proportion to the population of those who call themselves physicians varies greatly in different localities; thus, in Colorado there are 29.3, in Indiana 25.2, in Oregon 24.3, and in Arkansas 23.5 per 10,000; while in New Mexico there are only 6.6, in South Carolina 9.2, and in North Carolina 9.7 per 10,000.[1]

It is not easy to give satisfactory reasons for these differences; we can only say that they do not depend to any great extent upon local legislation. The proportion of physicians is generally lowest in the southern States lying east of the Mississippi, and highest in those regions where immigration has recently been active. If we compare, by localities, the proportion of physicians to the population with that of clergymen and lawyers, we find some curious differences. It seems that the lawyers in the United States number 12.7, while in England and Wales they are 6.6 per 10,000, but that on the other hand the clergymen are 14.6 in England and 12.8 in the United States per 10,000 of population. In many instances it seems that where the lawyers are most numerous the supply of clergymen is smallest. I believe that a fair proportion of physicians to population is about 1 per 1000, which is not far from the actual proportion in England, while the true proportion of practising physicians in the United States is about 1 in 750. We must admit then, that there is at all events no scarcity of physicians in the United States, and, as we have over eighty medical schools at work, besides a fair proportion of medical immigrants, there is no immediate danger of any interruption to the supply.

Let us now consider the second head of the complaint, viz., that the standard of education is too low. There is ground for this, considered with reference to some localities, but not for others. I said a moment ago that a man might be fairly qualified for practice in one part of the country and yet find himself at a loss in another. This needs a little explanation, which I can,

Chart I.



Map of the United States showing the distribution of deaths from malarial fever as compared with total deaths from known causes. Census of 1880.

[1] A map of the United States was here shown, on which the proportion of persons calling themselves physicians to the population in the several States was indicated by different shades of color.

perhaps, give most easily in connection with a map of the United States, which I here show you. This map, which was prepared for a very different purpose, indicates by different shades of color, the relative proportion of deaths reported as due to malarial disease to the total number of deaths in different parts of the country, for the census year 1879–80. You will note how comparatively light the tint is in the north and northeast, and how dark the shades become in the south and in the valley of the Mississippi, thus indicating the great differences which exist as to the prevalence and deadly effects of the malarial poison in different sections of the country. It is in some of these low bottom lands and swampy districts that we meet with cases of congestive chills and of malarial hæmaturia, cases in which the patient has been described as being "a mere appendage to a huge malarial entity, an incident of a miasmatic cataclysm." Furthermore, this strip of land bordering on the Gulf-coast is in the yellow fever zone, and has, heretofore, been repeatedly desolated by this pestilence.

As compared with the North and East, much of this malarious region is a thinly settled country, an almost purely agricultural country, and not a rich country. I need hardly tell you that the physician who has received his chief clinical instruction in the office of his preceptor in Vermont or New Hampshire, supplemented by distant glimpses of a few cases in hospital in Boston or New York, will find himself at a loss at first in dealing with the emergencies of daily practice in Arkansas and Mississippi. He will be subjected to influences which at times are dangerous to one who is not acclimated, and which tend to produce depression of spirits, want of energy, and bad health. He will not have free and constant access to scientific companionship, nor be stimulated by the influence of learned societies, and he cannot avail himself of the ordinary sources of amusement, education, and rest, such as art galleries, the drama, libraries, and museums, etc., which are found in the large cities. Moreover, the pecuniary reward which the practitioner in many of these places can reasonably hope for is comparatively small.

Taking all these things into consideration, it is clear that if a man after spending from six to eight years, and from one to two thousand pounds in acquiring such a general and professional education as it is now considered that a skilled physician should possess, then settles in such a region with the prospect of an average income of from £150 to £200 per year, it is not from pecuniary motives alone. There are such men in such places, men who are not only highly educated and skilled practitioners, but who are also original investigators and thinkers. It was within the limits of this malarial shadow that the foundation of modern gynecology was laid by Marion Sims, of abdominal surgery by McDowell, Battey, and Gross, of an important part of the physiology of the nervous system by Campbell. Nevertheless the rule holds good that malaria and science are antagonistic; the exceptions prove the rule.

Nor can the inducements for highly educated physicians to settle in thinly settled localities be made stronger by any form of penal or restrictive legislation. Any attempt to fix a standard of requirements or qualifications for practice which shall be the same for such rural districts and for the large cities and manufacturing towns, must result in the adoption of what competent judges would consider so low a standard as to be ridiculous and useless. The demands are widely different, and corresponding differences exist in the sources of supply—that is, in the medical schools.

There is a class of medical schools in the United States whose object is to give the minimum amount of instruction which will enable a man to commence the practice of medicine without much danger of making such serious and glaring blunders as will be readily detected by the public. There are other schools whose aim and object is to make fairly well trained practitioners; the general character of the instruction given in these being substantially the same as that given in your English hospital medical schools. The results of such a three years' graded course of instruction in medicine as these schools furnish, depend upon the character of the material upon which they work; that is to say, upon the general preliminary education possessed by the student at the time of his matriculation. This is evidently too often defective, and only a few schools have thus far ventured to establish any standard of preliminary examination which at all approaches in its demands that which is required in England.

The proverb that it does not pay to give a $5000 education to a $5 boy is clearly of American origin, and sums up a great deal of experience.

You have nineteen portals of entrance to the profession and have not found it easy to keep them all up to the standard. In America we have over eighty gates, a number of turnstiles, and a good deal of the ground is unenclosed common. Many of our physicians are more or less dissatisfied with this state of things and with the results thereof, and every year in some States efforts are made to secure legislation which it is supposed will protect the interests of the profession, though those who advocate such legislation are usually prudent enough to claim as their only motive a desire for the protection of the public.

Now, how does this free trade in medicine and the low standard of qualification or no standard at all required by law affect practitioners as individuals? To answer this we must divide the profession into several classes. In the first place, in all our cities, great and small, there is a large class of physicians who are as well educated and as thoroughly competent to practise their art, as can be found in the world. They have studied both at home and abroad, have had extensive clinical training, are always supplied with the latest and best medical literature and the most improved instruments, and many of them are connected with hospitals and medical schools. Among them are found the majority of our writers and teachers, and the successful men are the survivors of a struggle in which there has been keen and incessant competition. These physicians, whose positions are fairly assured, and who, as a rule, have all the practice they desire, are not usually active leaders in movements to secure medical legislation, although they passively assent to such efforts, or at least do not oppose them; and their names may sometimes be found appended to memorials urging such legislation. They are clear-headed, shrewd, "practical" men, who know that their business interests are not specially injured by quacks and ignoramuses—rather the contrary in fact, for they are called on to repair the damage done by the quack to people who have more money

than brains; and they are not inclined to risk the fate of the Mexican donkey who died of "*congojas agenas*"—that is, "of other people's troubles."

Then there is another large class of honest, hard-working practitioners who rely more on what they call experience and common sense than on book learning. Many of these have obtained assured positions of respectability and usefulness, and are comparatively indifferent to medical legislation so far as their own interests are concerned. Others, however, who are not so successful, feel the competition of the local herb doctor or of the travelling quack more keenly, and have more decided views about the importance of diplomas. Among these are the young men who have not yet acquired local fame, and who are apt to become very indignant over the doings of some charlatan in the neighborhood, or of some druggist who prescribes over his counter. These last are usually quite clear in their minds that the State ought to interfere and prevent injury to the health of the people.

I have known two unsuccessful physicians who finally abandoned practice and who gave as a reason for their failure—one that "he did not know enough," and the other that "he had not the manners and tact which would inspire confidence in his patients;" but such frank-speaking men are rare.

Thus far, as a rule, the efforts which have been made to secure legislation upon medical matters in America have come from the profession itself and have been chiefly urged and recommended by physicians. The general public, and even the educated public, has shown very little interest in the matter. It does not demand protection against ignorance, but entrusts the care of its health and the lives of those who are nearest and dearest to it to almost any one who announces himself as prepared to take charge of them. The number of those who profess to practise medicine in the United States and are not qualified to do so is undoubtedly large, though by no means so large as one might suppose after listening to the impassioned eloquence which is duly aired every year upon the subject. There are some advertising charlatans, and travelling quacks are occasionally to be met with, but they are rare.

The most rigid tests of qualification, in our profession, in the United States are those required of candidates for admission into the medical departments of the army and navy. The standard established for these is about the same as that for the corresponding corps of the English army and navy; and of the candidates who apply, from seventy to eighty per cent. are rejected.

Certainly we must admit that this percentage indicates an unsatisfactory state of things. But what evidence have we as to its results upon the health and life of the people? What shall we take as the measure of the difference of skill in physicians? The death-rate? If we compare the death-rate of the United States with those of other civilized countries, we find that it is as low as any with the exception of Sweden. Does a low death-rate mean better sanitary condition or more skill among the doctors? For the last twenty years the death-rate has been diminishing in England; the average amount of life for each person here has been increased, but I observe that the sanitarians claim this as proof of the value and importance of their efforts, and that nothing is said about its being in any way due to increase in medical skill or to improvements in medical science. Evidently this test is not a convincing one. Almost the only matter in which figures seem to demonstrate the importance of superior medical education and skill is in the statistics of deaths due to childbirth and of the results of surgical operations.

The proportion of deaths from childbirth to the number of births is decidedly greater in the rural districts than in large cities, and among the colored than among the white population. If this difference were found only in the United States statistics, it might be accounted for by the differences in the trustworthiness of the sources from which the data are derived; but we find similar differences in England, and we must admit that these are probably largely due to the fact that in cities labor cases receive more prompt and efficient professional care than they do in the country. I need hardly call your attention to the results of antiseptic surgery, or of modern abdominal surgery, as compared with those of twenty-five years ago. Here there can be no question as to the improvement. It is well to remember in this connection that whatever undue prolongation of disease or unnecessary mortality is due to want of skilled medical treatment occurs mainly among the wage earners, the farmers, mechanics, salesmen, needlewomen, etc., and not among the rich, nor yet among the very poor.

Now, seeing that really efficacious legislation with regard to medical education or to the practice of medicine must, like all efficacious legislation, be substantially in accord with public opinion, since it is impossible to continue to punish for any length of time that which public opinion does not condemn; and as the great mass of the people of the United States have not as yet had such evidence as they can understand, and which would thoroughly convince them that it is to their interest to suppress quackery, it follows that it is necessary to go slowly and to allow such evidence to accumulate.

To me it seems that the most important of the first steps to be taken in this direction is one which has already been taken in Great Britain—namely, the requirement that every death in the community shall be registered, and that in such registration satisfactory evidence shall be given as to the cause of death, sufficient at least to prove that such cause is what is known as a natural cause—that is, that it is not due to crime. When it is admitted that one of the duties of government is to provide for such registration, both in the interests of life and to secure the rights of property, it follows, necessarily, that those persons whose certificates as to the cause of death are to be accepted as satisfactory evidence that there has been no foul play, must present evidence that they are properly qualified to make such certificates. The principle is precisely the same as that which induces a government to provide for the examination of the medical men whom it employs in its army and navy.

So far as the art of medicine is concerned, the demand has much, though by no means all, to do with regulating the quantity and quality of the supply; and there are few localities in the United States where the qualifications of the medical man is not fully up to the standard which the community is able to appreciate and is willing to pay for. In the natural order of things, suffering and death are the remedies for ignorance, weakness, and vice, and the means of preventing the transmission

of these characteristics to offspring. These remedies, though effectual, are drastic, and we do our best to avoid them, but perhaps it is well that the penalties cannot be done away with altogether.

The laws regulating the practice of medicine in the United States are all State laws. If we were to judge only from what may be found in the statute books, assuming that all the laws contained therein are duly enforced, we should find that nearly two-thirds of the States have laws ostensibly regulating the practice of medicine within their borders. As a matter of fact, however, in over half the States which have laws on this subject no attempt is made to enforce them, and in almost all of them the possession of a diploma, no matter from what source derived, is all that is required.

Of the various methods which have been tried in different States to insure by law that physicians shall be properly qualified, I will call your attention to two which are of special interest.

The first is that of Alabama, the principle of which is to organize the whole medical profession of the State, and use it as the means of regulating the qualifications of practitioners and of caring for the public health. The Medical Society of the State of Alabama with its branches, the county medical societies, thus forms a part of the machinery of the Government; it appoints boards of medical examiners, selects State and county sanitary officials, supervises the registration of vital statistics, the administration of quarantine, etc., — in short, it is the State Board of Health, and the county branches are the county boards of health.

In this State the possession of a diploma does not give the right to practise, it simply enables the owner to go before the examining board. The examinations before the County Board are partly in writing, and are subject to review by the State Board, which has in some instances publicly condemned the local examinations as not sufficient.

This system has now been in operation nine years, and has gradually been consolidated and improved by educating local boards, and getting all physicians interested in it, until it is now working fairly well. Much remains to be done, and it is too soon to predict results; at present, the success of the system is largely due to the wisdom and energy of one man, who has given his whole time and labor to the work, and it remains to be seen whether the machine which he has built will work well without him.

The second system to which I will call your attention, is that of the State of Illinois, which was commenced in 1877, or about the same time as that of Alabama.

In Illinois any one who presents a diploma, or license to practise, from a legally chartered medical institution in good standing, is entitled to practise, and the State Board of Health is to decide as to what shall constitute "good standing." The Board of Health also examines all persons who do not possess satisfactory diplomas, and who nevertheless wish to practise in this State.

One of the greatest practical difficulties in the way of providing any system of State examinations in medicine in the United States, is that public opinion will not support any law which can be supposed to condemn or in any way to injure homœopathic and eclectic practitioners or their schools, and hence any proposed law relating to medicine, or to the organization of State boards of health, which does not recognize the existence of these sects will, in many States, at all events, meet with enough opposition to defeat it. In Illinois this difficulty was surmounted by the arrangement, that of the five physicians on the Board, one should be homœopathic and one eclectic. The Kansas law, passed last year, goes further in this direction, and provides that appointments must be so made that no school of medicine shall ever furnish a majority of the members of the Board. Much to the surprise of many, the Illinois plan has worked very well—there has been no quarrelling in the Board—and the homœopathic and eclectic members seem to have upheld quite as high a standard of qualification as their fellow members. The results of the work in Illinois have been very good. A large number of ignorant charlatans were forced to leave the State. The requirements of the Board as to what shall constitute a medical college in good standing have been raised, and it has thus caused improvement in the medical schools, not only of Illinois, but of other States. Moreover, the neighboring States have been stimulated to action, not only by the force of example, but because they received the men who had been driven out of Illinois, and found the accession an unpleasant one.

As in the case of Alabama, it is too soon to judge definitely of the results; and in Illinois, also, the satisfactory working of the system is largely due to one man, the Secretary and executive officer of the Board, who has given his entire time to the work. I do not, by any means, wish you to suppose, however, that I consider this as being a serious objection to this or any other plan, for in the building up of any organization, or the carrying out of any system, much must always depend upon some one man.

The relations of the United States Government to medical education and to the practice of medicine are indirect only, the regulation of these matters by law being part of the police power which, under the constitution, is reserved exclusively to the individual States. The United States employs physicians in its Indian Department, in the Pension Department, in the Marine Hospital Service, and in the medical departments of the army and navy, and it has power to regulate the practice of medicine in those territories which are not yet organized into States, and also in the District of Columbia; but thus far it has made no use of such power. The qualifications of physicians employed in the army and navy and in the Marine Hospital Service, are determined by examinations made by boards of medical officers belonging to those services. The possession of a diploma from a respectable medical college is a prerequisite for such examination, but beyond this it does not count; that is to say, the examination is the same for the holders of all diplomas, and covers all branches of medicine. But while the relations of the general government to medical education are thus indirect, they have of late years become of very considerable practical importance, and are now exerting much influence upon medical investigations and literature. This is being effected by the museums and libraries which are now being formed under the auspices of the government at Washington, and also, to some extent, by certain special investigations undertaken by the government in the interests of preventive medicine. Of these various agencies one of the most important is the library which

has been formed at Washington, under the auspices of the medical department of the army in connection with the Army Medical Museum; both of these institutions being a part of the results of the late civil war. The museum was at first formed to illustrate military medicine and surgery, giving the results, primary and secondary, of injuries inflicted by modern weapons of warfare and of the diseases of armies in the field; in which direction the collection is unrivalled in extent and completeness. Gradually its scope has been enlarged to include illustrations of anatomy, development, and all branches of pathology and therapeutics, so that it is fast becoming a museum covering the whole field of medical science. In like manner, the library, which commenced in a collection of those books relating solely or especially to military medicine and surgery, which were required in the compilation of the *Medical and Surgical History of the War*, has expanded into a great medical library, which is now one of the best practical working collections of the kind in the world. These collections, then, no longer appertain exclusively, or chiefly, to the business of one department, but belong to the whole profession of the United States as a body; and the department which has charge of them is managing them from this point of view. The influence of the library in stimulating research, and upon the quality of medical literature, is already very perceptible, and is destined to increase with advancing years. I think I may also venture to claim that the utility of these collections, and especially of the library, is by no means confined to the medical profession of the United States, for the catalogues and indexes which are being issued in connection with them, are of service to medical writers and teachers all over the world.

As regards investigations into the causes of disease, undertaken at the expense of the general government, only a beginning has as yet been made; but it is sufficient to indicate future possibilities and probabilities. The main importance of the work of the National Board of Health, which was organized in 1879 under the stimulus of the great yellow fever epidemic of the previous year, was due to investigations upon the causes of yellow fever and diphtheria, the relations of soils and of water-supply to certain diseases, etc., investigations of the same general character as those which are being prosecuted under the auspices of the Local Government Board in this country, and of the Imperial Board of Health of Germany. It is true that owing to circumstances which I cannot here explain, the work of the National Board of Health has been stopped; but there is every probability that it will be resumed, with perhaps some change of organization, at no distant day, and I need not dwell upon the vast importance to medical science of organized and systematic work in this direction. Similar investigations have been undertaken by State boards of health, and especially by the State Board of Health of Massachusetts, and the fact that governmental health departments are tending to work in this direction is significant as to future coöperation from such sources.

In this connection should be mentioned the National Museum of Hygiene, which has been formed under the direction of the medical department of the United States Navy, which is now one of the most instructive collections of the kind in the world, and has also connected with it an excellent library and a well-equipped laboratory.

Comparative and experimental pathology is also receiving attention from the Government under the direction of the Department of Agriculture, which is doing some good work in the investigation of the diseases of our domestic animals. Our investigators are, fortunately, not hampered by antivivisection laws, and there is little danger that they ever will be, for though we have our due proportion of fanatics and seekers of notoriety who wish to emulate the British Antis-, their true motives are so well understood that they have little power to do mischief.

Of medical associations in the United States there are several classes. We have a few local societies, analogous to clubs in their organization, which own property in the form of buildings, libraries, etc., are somewhat conservative in their selection of members, and are only to be found in large cities. Of these, the College of Physicians of Philadelphia is the oldest, and has the largest and best library and museum—it will celebrate the hundredth anniversary of its existence next year. In New York the Academy of Medicine, and in Boston the Medical Library Association, are of the same character, and, in general, each large city has a similar society, although as yet they have not become fully anchored and established by the acquisition of property. The second class includes local societies devoted to specialties, such as pathology, obstetrics, etc. These also are found only in large cities, and as yet are few in number. Four of them only have published transactions. Corresponding with these are national societies devoted to specialties such as gynecology, ophthalmology, surgery, pathology and clinical medicine, etc. These societies meet annually, elect their own members, exercising care in the selection, and publish valuable transactions.

Another class is composed of the county medical societies, which strive to include all regular practitioners residing in their precincts. From these are sent delegates who form the State medical societies and the American Medical Association. The mode of organization varies somewhat in the different States, but the representative principle prevails in all. Most of these societies publish transactions, and the American Medical Association now has its journal.

As to the condition of medical science and art in America, it partakes of the general progress, for the press now makes all discoveries the common property of the civilized world. The marked feature of the present epoch is the recent advance in knowledge as to the relations between microörganisms and certain diseases, and the strong stimulus which this has given to preventive medicine. Sanitation is becoming fashionable, and if we may believe some of its votaries, it is a very simple matter to prolong the average lifetime to the scriptural "three score years and ten." All that is necessary is that everything shall be clean, and every person virtuous.

Having learned to distinguish those diseases which can be prevented much more easily and certainly than they can be cured, we may turn them over to the sanitarian, who has his own battles to fight with ignorance and prejudice. If he succeeds, and so far as he succeeds, he will change, in certain respects, the work of the practitioner.

The lives which are saved from cholera and typhoid, from consumption and diphtheria, and from the acute specific diseases, will, at last, be weakened and destroyed in other ways. The work of the physician will not be lessened by preventive medicine, it will simply be required more for older persons, and for another class of diseases. As sanitarians must depend upon practitioners for much of the information which is essential for their work, it follows that if preventive medicine is to become a working power, it will bring the mass of the profession into closer relations with the State than its members have held heretofore. What these relations shall be is one of the most interesting, and, at the same time, one of the most difficult, of the many problems with which we, or our successors, must deal. I have referred to some experiments on this subject which are now being tried in America, where it is much easier to make such trials than it is an older country hampered with vested interests.

Just at present, in this, as in a number of other things, our tendency is toward centralization, both in the several States and for the whole country, and it is not improbable that we may go far on this road in the future.

I come now to the consideration of the second part of my subject, namely, the direction or manner in which we have reason to hope that medicine will be developed in the United States, and the kind of coöperation which you may reasonably expect to receive from the medical profession of that country.

A marked feature of the present day, in medicine as in other things, is the tendency to specialization in study and in practice. But this very development of specialties, of increasing minuteness in the division of labor, increases the necessity for coöperation, and in fact tends to create what we may call the specialty of coöperation. Formerly a rifle, or a watch, was made by a single workman. No two instruments were exactly alike, each piece had its own individuality and was not interchangeable, and the cost of the whole was such as to put it beyond the reach of the multitude. Now, the work on these things is greatly subdivided, one man makes only one small wheel, or spring, or pinion, and another another, each doing his work according to a uniform pattern, rapidly, perfectly, and at comparatively small cost.

But, in addition to the workmen who make the individual parts, it is now necessary to have one person specially skilled in making drawings and preparing patterns, another to assemble the completed parts, and a third, to test the whole after it has been put together. As the centrifugal force increases, the centripetal power must also increase.

In one sense medicine, as we have it to-day, is the result of coöperation, not of deliberate, centrally planned and direct coöperation, but of natural selection from results produced by many men, often working at cross purposes and, therefore, wasting much energy, but nevertheless working, though blindly, to a common end. And it is safe to predict that in the future much of the best work will be done in the same way, by individual effort inspired by the love of science, by personal ambition, etc. But the results obtained in this way come slowly, and some things that we want can hardly be obtained by individual effort, even if we were willing to wait, hence we must look to organization for help.

This is an age of machinery, of exchanges, of corporations, for all these correspond to one and the same fundamental idea. Men make machines to do what the individual cannot do, and they make them not only of brass and iron, but of men, for such an obvious source of power to the man or men who can master the combination is not likely to be overlooked. One result of such organization is seen in our encyclopedic works on medicine, whether these be called dictionaries or handbooks; another in the great medical journals; another in associations which seek to wield political influence; another in the comparatively recent attempt at collective investigation of disease. With these may be classed also the attempts of Government departments to make scientific investigations, to collect libraries and museums, to do things which require long continuity of effort on a definite plan in order to produce the best results.

And it is by the combination of all these, with the efforts of individual workers, that substantial advance and improvement are to be effected.

In this broader view of coöperation it is interesting to consider those fields of labor to which comparatively few physicians can devote themselves, because of want of time and opportunity, but whose proper working is, nevertheless, of the greatest importance to the practitioner.

One of these is experimental laboratory work, and in this direction the prospect of valuable contributions from America is now exceedingly good. Some of the wisest of our most wealthy men have shown their appreciation of the responsibilities which riches entail on their possessors by seeking new channels through which to benefit their fellow men. While the old and well-known methods of endowing hospitals and charitable institutions are not neglected, there is apparent an increasing tendency to endeavor to promote the advancement of knowledge, and especially of such knowledge as tends to the mitigation of suffering and the improvement of the race, to furnish means for the investigation of disease, to provide laboratories, and to endow medical schools and thus place them beyond the reach of the temptations and difficulties which must always exist when such schools are dependent upon the fees of students, and are, therefore, practically commercial manufacturing establishments.

As illustrations of this tendency, I may mention the bequest of £1,400,000 by Johns Hopkins to endow, in the city of Baltimore, a university and a hospital of which the medical department is to be a special feature, to be provided with the best laboratory and other facilities for original investigation as well as for teaching; the gift of Mr. Carnegie to the Bellevue Hospital Medical School of New York in the shape of a well-equipped pathological laboratory; the presentation by Mr. Vanderbilt, and members of his family, to the College of Physicians of New York, of £200,000, to provide for that school new buildings and clinics having the best means of teaching and research, and the endowment by an unknown donor, of a laboratory for the University Medical College of New York, with the sum of £20,000.

Last year, in his retiring address as President of the New York Academy of Medicine, Dr. Fordyce Barker referred to this tendency to regard wealth as a trust to be used for the benefit of humanity, and after sketching

the requirements of the Academy on a scale which would require an endowment of at least a million of dollars, predicted that such an endowment would be furnished by wealthy citizens of the city. I believe that he was right, and that his prediction will become history.

As the class of men who have wealth, leisure, and knowledge becomes greater, there comes an ever increasing demand, not only for the best medical skill, for the most expert practitioner, but also for exhaustive research in every direction which promises to furnish new means for the prevention or relief of suffering, and for warding off, as long as possible, the inevitable end; and hence there is little reason to doubt that the examples I have named will be followed by others in the near future. With such opportunities, and under such conditions and influences, the stimulus to the young and ambitious worker is strong; we have abundance of material of this kind upon which the process of natural selection can operate, and there is little reason to doubt that the result will be substantial and valuable contributions to physiology, pathology, and therapeutics.

I have already referred to some of the work which has been undertaken by the United States Government for the benefit of medicine and of the medical profession in the formation of a library, and the providing of means of assistance in bibliographical research. There is another most important means of advancing medical and sanitary science which only a Government can furnish, and in which field of work England now stands preëminent—I refer to vital statistics. In this field, the United States Government has thus far done but little, yet enough to show the great interest and value of what we have a right to hope will be done in the future by combining the work of the several States. This is one of the fields in which international coöperation is most desirable; it alone can furnish data sufficiently complete and reliable for a scientific consideration of the relations of disease to geographical and race distinctions.

Geographical pathology is a very old branch of medicine, as old, at least, as Hippocrates, whose treatise on airs, waters, and places is justly famous. Permit me to remind you of its opening clauses. "Whoever wishes to investigate medicine properly should proceed to consider the seasons of the year and what effects each of them produces, the winds, the qualities of the waters, the situation and exposure of the city, the character of the ground, and the mode of life of the inhabitants." Then, says the wise old Greek, "From these things he must proceed to investigate everything else."

There is a breadth of view in that last sentence which is particularly satisfactory. Since the days of Hippocrates there has accumulated a vast amount of literature relating to the supposed connection between the topographical peculiarities of different cities and countries, and the diseases which prevail in them, but when the books and essays which come under the heading of "Medical Topography" are examined, it will be found that the topographical part is much more complete than the medical—which last is mainly confined to the consideration of malarial diseases, and is vague and indefinite with regard to their relative prevalence.

Much the larger part of our really valuable information on this subject has been obtained within the last twenty-five years, as Prof. Hirsch points out in the preface to the recent edition of his very valuable handbook of geographical and historical pathology, and while the contributions of the United States to this branch of medical science have been already important, I hope to be able to show you that they are probably destined to be of steadily increasing importance in the future. Considered, as a body, the opportunities of the medical profession of the United States for the study of the manifold influences which can cause, modify, or prevent disease, are in some respects unequalled. As regards peculiarities of climate, soil, altitude, etc., the country is so large as to afford almost every variety of combination, so that nature may be said to be making a series of experiments, on a grand scale, upon the mass of humanity which is so rapidly increasing in the new world. Especially is this the case with regard to the problems of heredity as connected with the mysterious relations of certain forms of disease to race. America is at present the great mixing bowl into which are pouring streams of human life from origins the most diverse, from regions the most remote. Black and white, red and yellow, long skulls and short skulls, Celt, Teuton, and Slav are being brought together under similar conditions of climate, food, and occupation, thus permitting of the comparison and study of the different effects, if such exist, which result from variations in parentage under conditions of exposure to the same causes of disease.

For a little time, a generation or two at least, the different streams remain pure, then there is more or less mingling, in some cases very little, in others very intimate, but always there is an opportunity of studying the races separately, as well as of investigating the results of their various mixtures.

To illustrate the possibilities in this direction, I will call your attention to some peculiarities in the distribution of deaths from certain causes in different parts of the United States, and for this purpose I shall make use of the data from our last census, taken in 1880. We have no general and uniform system of registration of births and deaths. The larger cities, and about half a dozen States, have such a system, but for much the larger portion of the country the only means which we have for determining differences in amount or causes of mortality in different localities is through the census, which is taken once in ten years. The data thus obtained with regard to deaths are imperfect, because when these are collected, only at the end of the year, about thirty per cent. of the deaths are unrecorded; and they are inaccurate, because the reports of the causes of death are not furnished by persons competent to give reliable information with regard to them. Nevertheless, these data are the best that we have, and although for a large part of the country they do not give us the actual number of deaths from any cause or set of causes, they do furnish some interesting information with regard to the relative prevalence and importance of certain causes, and suggest questions and lines for future investigation, although they do not furnish definite and scientific answers.

Take, for instance, this map of the United States upon which, by varying shades of color, is shown the proportion of deaths reported as due to cancer, as compared with the reported deaths from all causes. Cancer, using the term in its broadest sense, is a disease which seems to be gradually increasing in frequency among

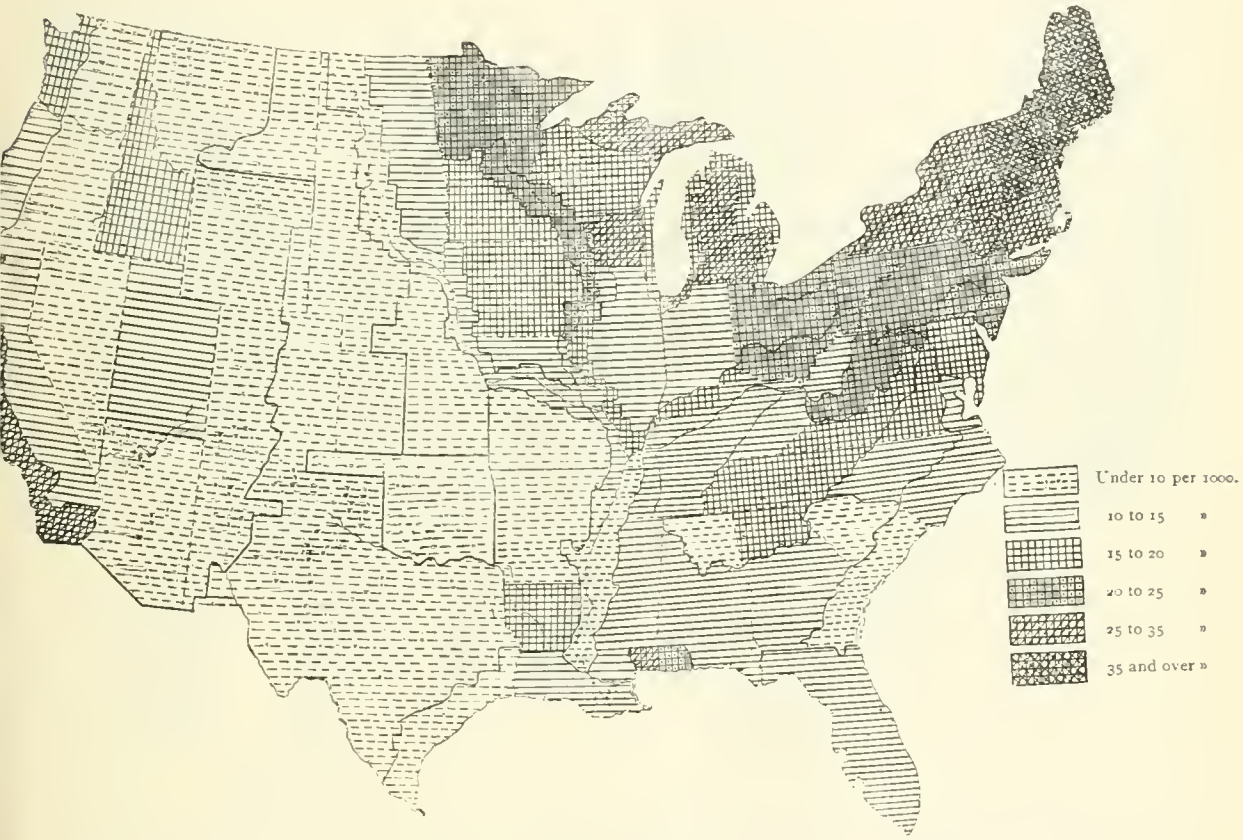
civilized nations, and, possibly, to have a tendency to increase with the advance of civilization.

In England and Wales the proportion of deaths from this cause seems to have nearly doubled within the last twenty-six years, and a similar rate of increase can be made out in certain parts of America. How far this increase is a real one, and how far it is due simply to improvement in diagnosis, is a question yet unanswered.

The mortality from cancer in the United States is proportionately greatest in the New England States, somewhat less so in New York and Pennsylvania, and it causes the least proportion of deaths in the Mississippi Valley and the South generally. The proportion of deaths from cancer in the United States is somewhat greater than it is in England; but it is not possible to make any accurate comparisons in this respect. Now why are the shades on this map so dark in the northeast and so light in the south? In the first place, cancer is a disease the mortality from which steadily increases with advanced age, as you may see from this diagram. Hence, cancer causes a higher proportion of mortality in those localities which have the greatest proportion of population living at advanced ages, and in the United States these localities are the New England States, as you will see by this map. One deduction from this which may perhaps not have occurred to all of you, is that a large proportion of deaths from cancer indicates, to a certain extent, that the locality in which it occurs is a healthy and long settled one, since it has probably a relatively large proportion of inhabitants, and especially females, of an advanced age. But another explanation of the peculiar shading of the cancer map is found in the relations of race to the tendency to death from this disease. The proportion of annual deaths from cancer per hundred thousand living population was, in round numbers, twenty-eight for the whites, and thirteen for the colored. That is to say, cancer is more than twice as prevalent among whites as it is among colored in the same localities, for these figures apply only to the South. On the other hand, cancer appears to cause a greater proportion of deaths in persons of Irish and German parentage, than it does among the rest of the white population, the indications being that between the ages of fifteen and sixty-five the Germans are especially liable to cancer; more so than the Irish, and decidedly more so than the average white population. Now when we remember that the greater part of the colored population is in the South, and the greater part of the Irish and German population is in the North, we have another reason for the differences in mortality caused by this disease in the two sections.

Again, take this map, showing the distribution of the

CHART II.



Map of the United States showing the distribution of deaths from cancer as compared with total deaths from known causes. Census of 1880.

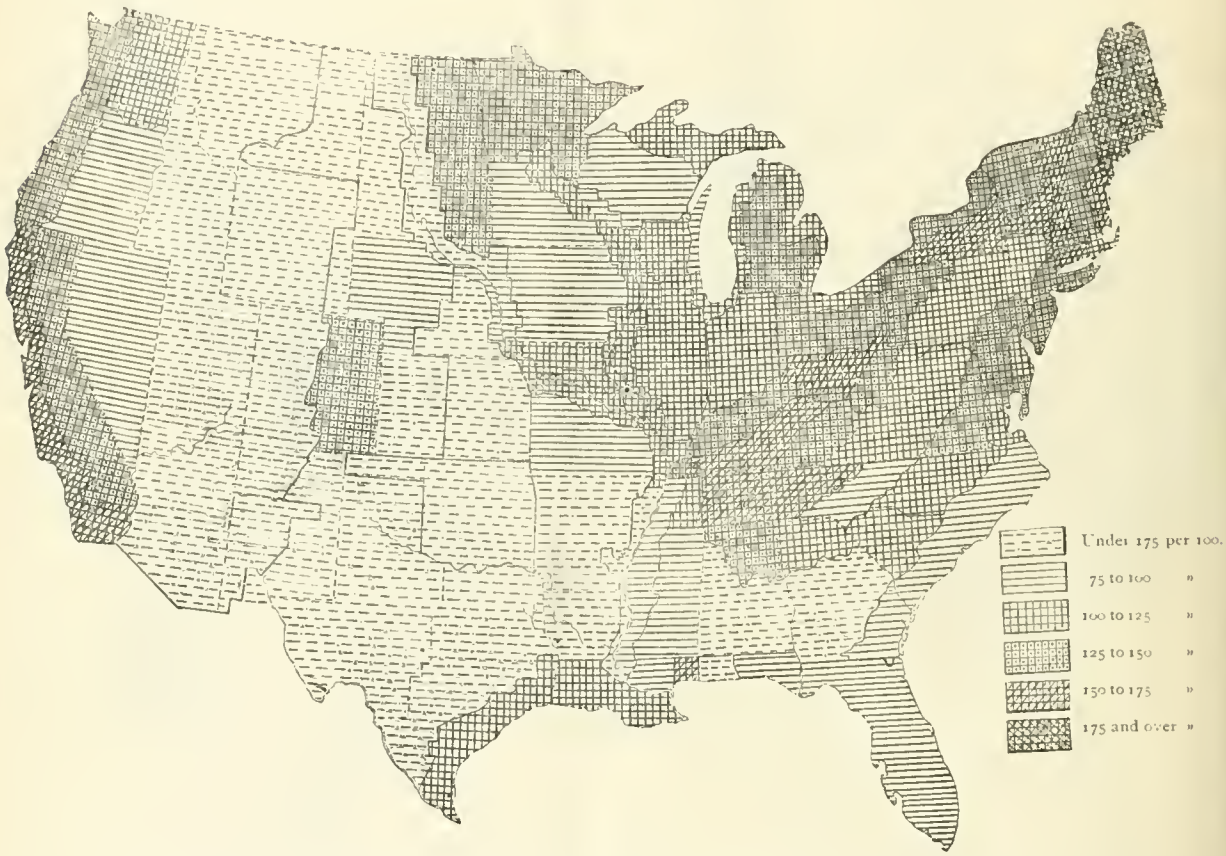
deaths from scarlet fever during the census year. You see that this also was most fatal in the North, and, here again, the influence of race comes in, because in the negro race the mortality from this disease appears to be very low. This disease has always been much rarer in the South than in the North, and the contrast was much stronger in former years than it is at present; but this cannot be explained solely, or even to any great extent, by difference of temperature, because scarlet fever has often been epidemic in the tropics, and, on the other hand, in many localities in temperate climates it is among the rarest of diseases.

again the influence of race comes into the problem, although, probably, only indirectly; that is to say, it is probable that it is the habits of a peculiar class of people which favor the propagation of the disease rather than any physical peculiarities in the structure of their bodies.

Two more illustrations of the geographical distribution of disease in the United States may be of interest in this connection. The first is that of consumption, the second, of pneumonia.

Consumption is a vague term, and, as used in the census, no doubt includes many cases which were not

Chart III.



Map of the United States showing the distribution of deaths from consumption as compared with total deaths from known causes. Census of 1880.

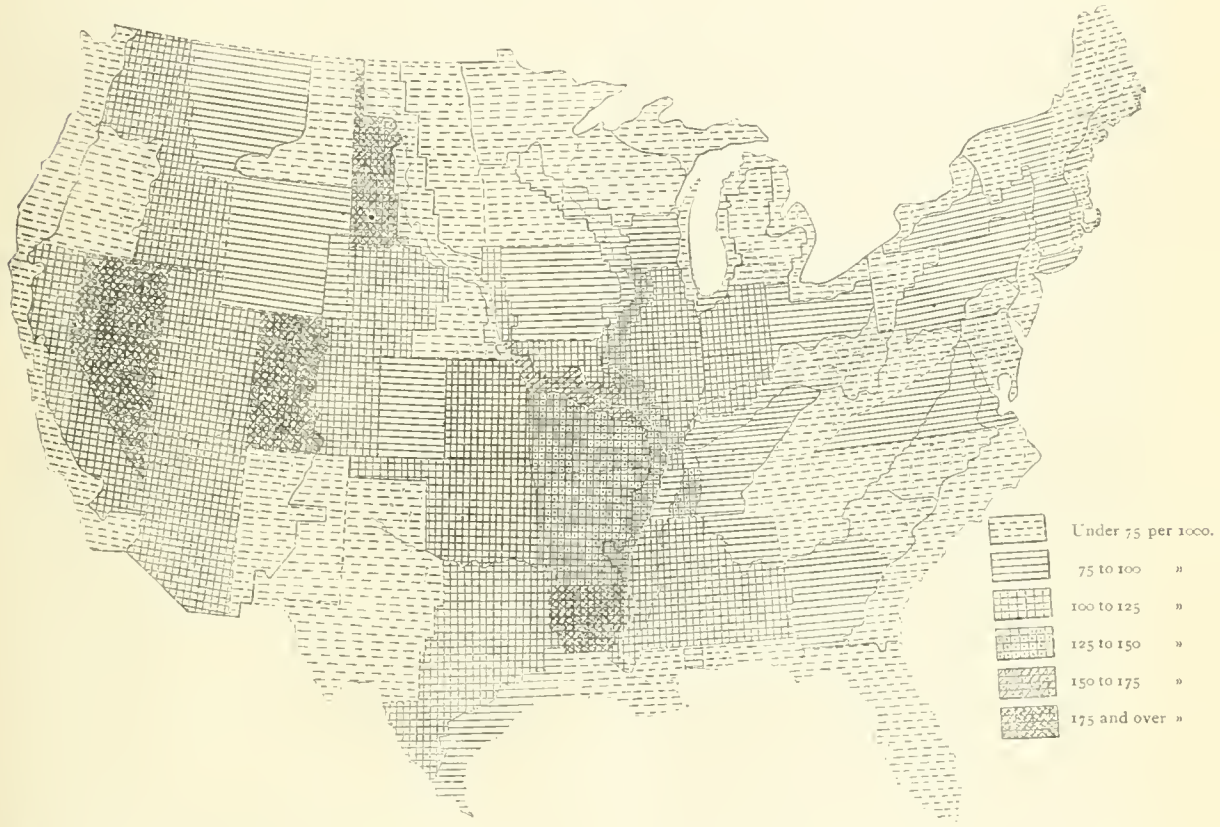
Here is another map showing the distribution of deaths reported as due to diphtheria during the year. Diphtheria is a disease which has been unusually prevalent in the northern portion of the United States for several years. During the census year it caused 2374 deaths out of every 100,000 deaths from all causes, while in England, for the year 1880, the deaths from diphtheria were 532 per 100,000 deaths from all causes; that is to say, the comparative mortality from this disease in England was less than one-fourth that of the United States for the same period. Dipththeria, again, is essentially a disease of the north, but especially of the northwest. It causes an excessive mortality in children of German parentage, sufficiently so to show that here

true tubercular phthisis. It is reported as causing twelve per cent. of all the deaths, or more than any other single cause. In England and Wales, in 1880, it caused a little over nine per cent. of all the deaths. Such wholesale ratios are, however, of little interest or value. There are very great differences in the liability to this disease in different parts of the United States, as the map makes sufficiently evident, and it is from a study of the causes of these differences in the data derived from large masses of people, combined with clinical histories and experimental laboratory work, that we have good reason to hope to obtain knowledge, not only of the causes of this disease, but of better methods of prevention and treatment than are now at our command. It

causes a greater mortality among the Irish than in other white races, and, perhaps, a greater mortality among the colored than among the white.

Next to consumption, pneumonia is reported as causing the greatest number of deaths in the United States during the census year, giving a ratio of 8.3 per cent. of all deaths, as against 4.8 per cent. in England and Wales in 1880. Here, again, the local distribution of deaths is interesting, and the contrast between the map of consumption and that of pneumonia is very striking. Here, again, we find that race peculiarity is an important factor in the problem, the proportion of deaths from

CHART IV.



Map of the United States showing the distribution of deaths from pneumonia as compared with total deaths from known causes. Census of 1880.

pneumonia among the colored being much greater than it is among the white.

I have elsewhere commented more fully than it is possible to do here upon these peculiarities of the distribution of certain causes of deaths in the United States.[1] In fact, my only object in calling your attention to the subject is to indicate the direction in which we may hope for good work hereafter, which indication is the chief, if not the only valuable result of the work already done. In the brief comments which I have made upon these maps you will have noticed the stress which I have laid upon race peculiarities. These race problems are simply problems of heredity taken in mass, and there is no need to urge upon an assemblage of medical practitioners the importance of considering family peculiarities in diagnosis, prognosis, and therapeutics. That the questions involved are difficult and complicated is true, but we are already possessed of more knowledge with regard to them than is commonly supposed.

In a lecture on "Life," delivered a few months ago, Prof. Brookes, of the Johns Hopkins University, illustrated this as follows: "If I am placed, with my eyes bandaged, before a stone lying free on the surface and am told to kick it, and if I know at the same time the size, shape, and weight of the stone and the character of the surface, I can form a pretty accurate idea as to what the result upon the stone will be. While if the object to be kicked is a dog, and I am given precisely the same data, I cannot tell what will be the effect. But if I can see the dog, I can, in many cases, predict pretty accurately. If he is a bulldog, he will do one thing; if he is a Gordon setter, he will do another." And, in like manner, the old family doctor knows that when a particular disease appears in his neighborhood, he may expect to see it produce in one family convulsions, in another collapse, and, in a third, little or no danger or inconvenience.

This kind of knowledge is, however, at present mainly confined to individuals, it has not become a part of the

[1] See report on Mortality and Vital Statistics of the United States as returned at the tenth census, 2 vols. 4to., Washington, 1885–1886.

world's knowledge; it is not defined; in other words, it is not scientific. To make it so, is the work of the future, and in this work I hope that we shall be able to help you.

I have spoken to little purpose if I have failed to show you that there is a great deal of human nature in American physicians, and that it is a kind of human nature with which you are tolerably familiar. It should be so, for we are of the same race, a race which, perhaps, as Emerson says, "sets a higher value on wealth, victory, and material superiority than other men, has less tranquillity, is less easily contented." Our ancestors were restless, fighters, freebooters, and from these ancestors we have the common inheritance of energy; of what *we* call "firmness," and our opponents unreasonable, pig-headed, stubbornness; of liking to manage our own affairs, and, at the same time, to exercise a little judicious supervision over those of our neighbors; of hatred of humbug, and lying; and, in spite of our discontent, of a firm belief that our wives and children, habits, houses, modes of business, and of treating disease are, on the whole, better than those of any other people under the sun.

Privately, and between ourselves, we grumble and declare that the country and profession are going to the dogs—nay, we must do so, or we should not be of true English blood, but there is no need for me to tell you that these are only "growing pains," and not symptoms of progressive ataxy.

While we must consider the difficulties in the way of the improvement of the science and art of medicine, difficulties due to ignorance, to indolence, to conflict of interests, and to the eternal fitness of things, the existence of such difficulties is not a matter to be bemoaned and lamented over. These obstacles are the spice of life, the incentives to action, the source of some of the greatest pleasures which it is given to man to experience.

The child, spending a happy hour with its new puzzle, is a type of the scientific investigator. The naturalist who objected to the statement that this is a miserable world which it is well to be soon done with, on the ground that there are still many species of rhizopods which he had not examined and classified, is another type. On the ethical and sociological side, the matter is summed up in Ruskin's aphorism, that "Fools were made that wise men may take care of them."

It is surely not without cause that there has been given to us this restless spirit of inquisitiveness, this desire to compass the heavens and the earth, this raging, infinite thirst for knowledge, it is the outcome of brain training and natural selection for thousands and tens of thousands of years.

We are in a period of the world's history characterized by material prosperity, by increase of populations, by tendencies to uniformity, to the making of individuals of small account. According to the Swiss philosopher, Alphonse de Candolle, this is to last a thousand years or so, after which the pendulum will swing the other way, and there will follow a long period of diminution and separation of peoples, and of decadence.

Against that decay of nations we know of but one remedy, and that is increase of knowledge and of wisdom. And this increase must be in *our* knowledge, in the world's wisdom, and not merely in that of John, or Fritz, or Claude.

As each man has special opportunities and duties, if he can only recognize them, so it is with guilds, with professions, and with nations.

I have tried to indicate to you some of these opportunities which are presenting themselves to my colleagues, your brothers, in the lands beyond the sea, and I hope that I shall not be considered rash, or vainglorious in saying that I believe they will so use those opportunities as to return compound interest for what they have received from the storehouse of our common inheritance. Force changes form and place, the stored energy of the soil of our plains and valleys has been coming here in the form of meat and grain, has appeared in muscle and brain, and in a hundred other shapes, but none has been destroyed; our loss has been your gain, and in our turn we have received full and fair exchange.

It is our part now to remember that there are not two springs in the year, there are not two periods of youth abounding in energy and desire, or of manhood's strength and self-poise, in the life of any man or of any nation, and for us, as for those who have been before us, the Kanuri proverb holds true, "*Kabu datsia, kargum bago*"—The days being finished, there is no more medicine.

REPORT OF AN EPIDEMIC OF GONORRHŒA CONTRACTED FROM RECTAL COITION.

By RANDOLPH WINSLOW, M.A., M.D.,
PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF BALTIMORE, LECTURER ON CLINICAL SURGERY IN THE UNIVERSITY OF MARYLAND.

The following cases came under notice in 1883 and 1884, and present no features rendering them worthy of record, except such as are dependent upon their unusual mode of origin. In a certain institution near Baltimore, a large number of boys of ages from nine to twenty-one years are collected, who are, with few exceptions, closely watched, and are seldom allowed out of the sight of an officer. No females are employed as domestics except two middle-aged women as cook and laundress. There is no chance for the inmates to have connecti n with women outside, as the grounds are surrounded by a high wall, and watchmen are stationed in various places to prevent unauthorized ingress or egress. Owing to rigid surveillance, it would be equally impossible for sexual relations to have been had with the two middle-aged women aforesaid.

Notwithstanding these conditions, during 1883 and 1884 numerous cases of urethritis developed amongst the boys, the origin of which for a long time remained a mystery. The authorities were confident that the boys who were the subjects of the disease had had no opportunity to have sexual intercourse with women, and the boys would only acknowledge such causes as straining, wearing the clothes of other boys, and masturbation. As the number of cases increased, the officers began to unravel the mystery, and finally the following facts were brought to light:

For a long time sodomy had been practised to some extent in the institution, but without any especially ill results in regard to health. The younger boys were generally selected to take the part of a

female, usually for some substantial benefit, as a piece of tobacco, candy, or other delicacy, or a reciprocity of the favor.

The gonorrhœal epidemic is supposed to have originated in the following manner: A boy who was on leave of absence contracted gonorrhœa from a girl, and was the subject of the disease when he returned to his duties. Previous to his recovery he cohabited with another boy, causing an inflammation of his rectum. I subsequently examined the rectum of this boy and found it red, painful, and inclined to bleed. At first defecation had been painful, but he had recovered in that respect when examined by me. Soon after the connection of these two boys, the latter granted like favors to a friend, who had no urethral disease at that time, and in a few days he developed the usual signs of gonorrhœa. Another boy appearing at this time with urethritis, attributed it to rubbing his penis against the organ of the first mentioned boy, whilst engaged in a mock copulation, but would not acknowledge having had rectal coition.

Thus case after case occurred without assignable cause, though in a few instances the boys confessed to buggery, and attributed the disease to it. Not all the cases were accurately recorded, and in fact it is probable that a number of boys never reported for treatment at all, but the following cases are known to have been treated, and are presented for what they are worth.

Case I.—Boy, seventeen years of age, has not been outside for three months, reported at hospital August 3, 1883, with a urethral discharge, which lasted several weeks, and finally yielded to copabia internally and boracic acid injections. No cause assigned for the disease.

Case II.—Boy, reported at hospital on September 15, 1883, presenting all the signs of gonorrhœa, consisting of pain, swelling of penis, discharge, and chordee. He attributed the disease to wearing the shirt of another boy who had contracted the disease outside. This mode of origin was denied by the hospital steward, who said the whole story was a fiction.

Amongst cases without further history are the following:

Case III.—Aged nineteen; gonorrhœa.

Case IV.—Aged eighteen; gonorrhœa.

Case V.—Aged sixteen; epididymitis.

Case VI.—Aged sixteen; gonorrhœa, attributed by the boy to masturbation.

Case VII.—Aged sixteen; gonorrhœa causing phimosis, which resisted all treatment until he was circumcised.

Case VIII.—Aged sixteen; epididymitis; no assigned cause.

Case IX.—Aged fifteen; gonorrhœa, moderate in intensity, and three weeks in existence when first seen.

Amongst the cases which can be traced more clearly is the following:

Case X.—Boy, aged thirteen; impubic, entered hospital in September, 1884, with severe urethritis. He admits having had rectal coition with a comrade four days previously, and says the discharge began the day following. He has now a free discharge of bloody pus from the urethra, with other signs of severe inflammation of the canal. This boy became quite ill with considerable fever, and subsequently a suppurating swelling formed over the wrist-joint, which I considered to be pyæmic in nature, and later abscesses developed elsewhere. After a protracted illness he recovered. I examined the rectum of the boy from whom he says he contracted the disease, and found it red, painful, bleeding easily, and inflamed. I inquired of one of the boys who acknowledged to both active and passive pæderasty, whether he submitted to the approaches of his friends from any gratification which the act gave him. He denied having any pleasure in acting the part of the female, and only allowed it for reciprocal purposes.

I regret that efforts were not made to discover the gonococcus of Neisser in the discharges from both the rectum and urethra in these last cases. As some of the cases were treated by another physician, I am unable to report their histories as fully as I would like, but they are corroborative of the method of origin enunciated above.

The epidemic ceased about January, 1885, owing to the strict watch kept upon the suspected boys, and the severe corporeal punishment inflicted upon those detected in the act of sodomy, although isolated instances are still occasionally discovered.

I am induced to present the above brief account of this outbreak of urethritis on account of its rarity from an etiological point of view. Whilst many authors mention the fact that the rectum may be occasionally the seat of gonorrhœal inflammation, none with whose writings I am familiar mention any case in which the disease has been reconveyed to the urethra by rectal cohabitation. Van Buren and Keyes simply mention in a foot-note that cases of rectal gonorrhœa have been observed by Allingham and Tardieu (Van Buren and Keyes, *Genito-Urinary Diseases*, 1874, p. 53) in prostitutes who practised sodomy. Otis (*Practical Clinical Lessons on Syphilis*, etc., p. 261) mentions gonorrhœa as "occurring exceptionally in the mucous membrane of the rectum." Esmarch (in Billroth and Pithas's *System of Surgery*, Vol. III. Part II. p. 69) says:

"A very acute catarrh with profuse secretion results from transportation of the contagium of gonorrhœa to the mucous membrane of the rectum. It occurs in women most frequently from the inflowing of the secretion from the vagina; but in men through direct infection in consequence of passive pæderasty."

Kelsey (*Diseases of the Rectum and Anus*, p. 69) makes a similar statement:

"Again the disease may result, both in men and women, from the habit of passive pæderasty, and in such cases will be due either to mechanical violence or to the inoculation with gonorrhœal pus. A true gonorrhœa of the rectum, whether caused in this way or by direct inoculation in women by pus which is passing over the anus from the vagina, is very rare. The diagnosis of gonorrhœal proctitis will rest upon the amount and purulent character of the discharge, and the existence of gonorrhœa of the vagina, or the confession of intercourse with a diseased person in men."

Again, on page 167, he says:

"During the height of the process the rectum is hot, red, swollen, and granular, and there is abundant purulent discharge issuing from the anus from time to time in clots."

Agnew also mentions the possibility of rectal gonorrhœa (*Surgery*, vol. ii. p. 469) as follows: "Of the susceptibility of the rectal mucous surface, there can be but little doubt." In the *Maryland Medical Journal* for June 1, 1882, Dr. John Morris reports a case of rectal gonorrhœa in a lady, which did not arise from unnatural practices. "The symptoms were pain, spasmodic contraction, and formication."

The above references to the subject of rectal gonorrhœa are about all that are accessible to me at this time, and from them we learn that the disease has been seen by a number of medical men, notwithstanding the dictum of Mr. Henry Lee, that "it is doubtful if gonorrhœa of the mouth, nasal cavities, and anus ever occurs" (Holmes's *System of Surgery*, vol. ii., Am. ed.). That other observers have seen urethral inflammation arise from this unnatural and filthy practice I can scarcely doubt, but I am unaware of any such observations. Hence, place these cases upon record as etiological curiosities.

No. 1 Mount Royal Terrace, Baltimore,
July 13, 1886.

OBSERVATIONS ON LEAD POISONING, WITH SPECIAL REFERENCE TO THE EXAMINATION OF THE URINE.

By CHARLES BINGHAM PENROSE, M.D.,
RESIDENT PHYSICIAN AT THE PENNSYLVANIA HOSPITAL, PHILADELPHIA.

The cases reported in this paper were admitted to the medical wards of the Pennsylvania Hospital during the service of Professor J. M. Da Costa, 1885–86.

Case I.—F. H., æt. forty-two, admitted December, 1885; had been a house-painter for thirty-two years. He never experienced any bad effects from his business until November, 1881, when he had an attack of colic and constipation. He treated himself with Epsom salts, and recovered in three weeks. He continued well until December, 1884, when a squamous eruption appeared upon the palmar surface of the right forearm. This was followed by itching and burning sensations under the nails of the right hand. He began to lose strength in the right arm, and two weeks later became unable to extend the right hand, or fingers, and a marked tremor appeared in the arm. The left arm was then attacked with weakness and similar paralysis. He suffered from pains about the wrists and ankles. The pain originated at the ends of the flexor muscles of the forearm and radiated to the fingers. He had burning sensations on the soles of the feet and cramps in the calves. Attacks of spasmodic contraction of the flexor muscles of the forearms began to occur almost daily, and during these attacks it was with great difficulty that the fingers could be straightened. Muscular weakness extended to the legs and throughout the body. He suffered from headache, giddiness, mental wandering, and occasional delirium. His eyesight, which formerly had been very good, became much impaired. All these symptoms appeared suddenly: and they reached their maximum in extent and intensity during the first month of the attack. Indeed, the mental wandering, giddiness, and tremor had much diminished before admission, though the man had been under no treatment.

When admitted to the hospital, this man walked with a weak and unsteady gait. His hands were claw-shaped; the fingers being flexed and inclined toward the ulnar side. The joints of the fingers and the wrist-joints were prominent. The left wrist presented the appearance of subluxation. The deformity of the hands resembled that seen in rheumatoid arthritis. The extensor muscles of the forearms and all the muscles of the hands were atrophied. The thenar and hypothenar eminences were flattened: in the right hand they were obliterated. The muscular mass between the metacarpal bones of the thumb and index finger had disappeared on both hands.

There was complete paralysis of the extensor muscles of the hands and fingers, and the grasp was very feeble. There was no paralysis of supination and pronation (cf. Duchenne, *L'Electrisation Localisée*, 3d ed., pp. 671–691). The deformity and weakness were so great that he could only with difficulty feed himself, and he was unable to button his clothes.

There was great muscular weakness in the legs and throughout the body, though there was no paralysis or atrophy of any muscles with the exception of those upon the forearms and hands.

He complained of pain in the finger-joints, and at the ends of the flexor muscles radiating to the fingers. The pain was greater on the right side, and was not increased by motion or pressure. There was also pain about the ankles, and the right external malleolus was tender on pressure. There was a slight tremor of the right arm. There was no response to the patellar reflex.

There was a very diffuse lead-line upon the gums, which existed on the inner and outer aspect of the base of every tooth in the mouth. There were also black patches on the mucous membrane of the upper and lower lips opposite the left canine teeth. The tongue was flabby and marked by the teeth. The breath was fetid. The bowels were constipated, though there was no colic. The pupils were contracted and sluggish.

No murmur was heard in the heart. The first sound was indistinct; the second was distinct at the aortic and pulmonary areas. There was no anæmia. The complexion was florid, and examination of the blood showed that the red corpuscles existed in normal quantity.

The cutaneous sensibility was diminished on all parts of the hands, arms, feet, and chest. The greatest diminution of sensibility occurred on the palmar surfaces of the last phalanges of the little finger of the right hand, and of the thumb and middle finger of the left hand. On the two latter fingers sensation was completely destroyed, a needle was thrust through the skin without causing pain. Since the beginning of the attack the middle finger of the left hand had felt numb and cold.

Faradic contractility was absent in the extensor muscles of the forearms, and in the muscles of the hands. All the muscles responded to galvanic stimulation, with the exception of those which form the thenar and hypothenar eminences of the right hand. In these muscles all forms of electrical stimulation failed to cause contraction.

Though galvanic contractility was diminished in the paralyzed muscles, yet there were no apparent qualitative changes. The cathodal closing contraction was in every case the greatest. Of all the paralyzed muscles the extensor ossis metacarpi pollicis had best preserved its electro-muscular contractility (cf. Duchenne, *loc. cit.*).

For some time after admission he complained of continual frontal headache and neuralgic pains about the inner angles of the eyes. At times he was unable to see, and everything looked dim and dark before him. He also suffered from spasmodic contraction of the flexor muscles of the forearms; and during these attacks it was necessary to use considerable force to straighten the fingers. About forty ounces of urine were passed in twenty-four hours. The specific gravity was 1.021. No albumen, sugar, or casts were found.

After this man had been under treatment for five days he was sent, for examination of his eyes, to Dr. George C. Harlan, Surgeon of the Eye and Ear Department of the Pennsylvania Hospital.

The following is Dr. Harlan's report:

December 8, 1885. States that his sight had not been so good as formerly for the last year, and has grown much worse recently. No pain or inflammation of eyes at any time, or any symptom other than diminution of sight. Vision in the right eye is now $\frac{10}{LXX}$, and in the left $\frac{10}{C}$. The ophthalmoscope shows no decided change in the appearance of the fundus, but on hypermetropic refraction, weak convex glasses (+ 1.5) improve the vision to $\frac{20}{XL}$. Color vision normal. The visual field in each eye is extremely limited concentrically. At a distance of ten inches there is no vision, even for form, beyond an area two and a half inches in diameter about the point of fixation, which is central. Repeated examinations by different examiners give always the same result.

15th. There has been decided improvement in both the acuteness and the area of vision, and some in the accommodative power. There is now in the right eye V. $= \frac{20}{L}$ without a glass, and $\frac{20}{XX}$? with + 0.75; and in the left V. $= \frac{20}{L}$ improved by + 1.25 to $\frac{20}{XXX}$. The field of vision in each eye, taken at ten inches, measures twenty inches in its horizontal diameter and fifteen inches in its vertical, with + 3 D. No. 1 S. is read at eleven inches.

18th. After careful testing under homatropin the refraction is found to be in the right eye + 1.25 and in the left + 1.75, and the vision $= \frac{20}{XX}$? The visual fields are still improving, and are now but slightly contracted.

26th. Visual fields normal. As the patient's vision had been impaired for some time and he was not aware of the contraction of the fields, it is not possible to obtain any exact information as to the time of its commencement. There is very little doubt, however, that the earlier disturbance of sight was due to hypermetropia rendered manifest by the failure of accommodation, and that the contraction of the visual fields, which disappeared so rapidly, was of very recent origin.

Case II.—M. H., æt. forty-nine, admitted December, 1884, had been working for three years in a paint factory, where he handled only metallic lead. Six months after beginning work he had an attack of colic and constipation, which lasted five weeks. After this he was well until two months before admission, when he was again attacked with colic and constipation.

When admitted to the hospital he was still suffering with colic. The tongue was pale and marked by the teeth. The face and conjunctivæ were pale. Examination of the blood showed that there were but one-half the normal number of red corpuscles. There was a diffuse lead-line upon the gums on both jaws. The bowels were very constipated. There was no wrist-drop, and no paralysis or weakness of the muscles; and the electrical reactions were normal. The pupils were contracted and responded to light. The pulse was weak. At the left base of the heart there was heard a faint systolic murmur propagated toward the apex. The feet were slightly œdematous. Fifty ounces of urine were passed in twenty-four hours: acid reaction; specific gravity 1.020; no albumen, sugar, or casts were found.

These cases differed materially from each other in regard to the parts attacked by the poison. In Case I. it was the nervous system which was affected; there was no colic, and no apparent blood change. In Case II. the chief manifestations of the poison were the derangements of the intestinal tract and of the blood.

Both cases were put upon the same treatment, which consisted in the administration of twenty grains of iodide of potassium three times a day, small doses of sulphate of magnesium and aromatic sulphuric acid, and frequent warm baths. In addition, Case II. received thirty drops of the syrup of the iodide of iron three times a day; while Case I. received small doses of strychnia, and the galvanic and faradic currents were applied three times a week to the paralyzed muscles. It was found that most benefit was derived from the interrupted galvanic current. For about twelve hours after the application of this current the patient was free from pain about the wrists and fingers, and there were no spasms of the flexor muscles.

The atrophied muscles rapidly improved in strength and size under this treatment, though two months passed before any reaction to electrical stimulation was apparent in the muscles of the thumb and little finger of the right hand.

Case I. left the hospital, cured, after five months of treatment. The black patches had disappeared from the lips, and there was a scarcely perceptible line upon the gums. His eyesight was much improved, and he was troubled but little by headache. The patellar reflex was normal. Sensation had returned, to a great extent, to the surfaces where there had formerly been anæsthesia. Muscular power had so improved that he was able to return to his business of house-painting.

Case II was discharged, cured, after having been in the hospital six weeks.

Examination of the Urine for Lead.—The urine has frequently been examined for lead in cases of lead poisoning, but the results obtained have not been satisfactory. On some occasions lead has been detected; on others, it has apparently been absent.

It is probable that in many cases the failure to detect lead has been due to faulty methods of examination, and in this connection there are several points to be remembered.

It is said that sulphuretted hydrogen does not precipitate lead when it is combined with albuminous substances, nor when it occurs in the secretions, in cases of lead poisoning—at least, when iodide of potassium had not been administered (Ziemssen's *Cyclopædia of the Practice of Medicine*). If the urine is evaporated to dryness and the organic matter incinerated, there is always danger of driving off some of the volatile compounds of lead which may be present. If lead is present in solution in the urine, it may be precipitated as a sulphate, as the urine is evaporated; and this is especially likely to occur if sulphates had been administered to the patient.

Lead may also be precipitated by the alkaline phosphates in the urine as di- and tri-plumbic orthophosphates.

Sulphate of lead is soluble in solutions of ammonium acetate containing an excess of ammonium hydrate. The phosphates of lead are readily decomposed by sulphuretted hydrogen.

Reeves's test (*Australian Med. Rec.*, Dec. 14, 1861) consists in administering to the patient iodide of potassium, and then soaking in the urine for five minutes after each micturition, a piece of sulphide of potassium tied up in a white rag. When the sulphide of potassium has been dissolved, the rag is opened; and, if lead is present in the urine, it is said that a black deposit of plumbic sulphide is found on the inside of the rag. This test is of no value unless the black deposit is analyzed for lead. Sulphide of potassium cannot be obtained pure in the solid form; it always contains a considerable amount of carbon, which is itself left as a black, insoluble deposit.

The following method was employed in examining the urine of the two cases of this report:

One gallon of urine was strongly acidulated with nitric acid, and slowly evaporated. As evaporation progressed, more nitric acid was added, and, by the time the solution was evaporated to dryness, all the urea had been destroyed.

The residue was dissolved in a small quantity of distilled water, acidulated with nitric acid, and filtered. There was in every case but a very small residue upon the filter paper. This residue, after having been washed with a solution of ammonium acetate and ammonium hydrate, was added to the filtrate; and the mixture was tested for lead with sulphuretted hydrogen, sulphuric acid, electrolysis, etc. The ammonium solution was then acidulated and tested for lead in a similar manner.

Three specimens of urine were thus examined from Case I. One specimen was passed before, and two after the exhibition of the iodide of potassium. Two specimens of urine from Case II. were examined after the exhibition of the iodide.

On no occasion was lead detected.

In both cases rapid improvement took place, and the black line upon the gums perceptibly diminished in extent and intensity, showing that lead was being eliminated by some channel, though apparently not by the kidneys.

As already mentioned, the results obtained by other observers with regard to the detection of lead in the urine have been very variable.

Kletzinsky (*Wien. med. Wochenschrift*, 1857) detected lead in the urine of only two out of fourteen cases of distinct lead poisoning.

Dr. Parkes (*British and Foreign Medico-Chirurgical Review*, 1853) examined four specimens of urine from a case of lead poisoning. The first two specimens had been passed before, the last two after, the exhibition of the iodide of potassium. Lead was found only in the last two specimens. In this case, however, the last specimens were examined by a much more delicate method than the first.

Dr. Sieveking (*Med. Times and Gazette*, 1857) examined three specimens of urine from a case of lead poisoning, during the exhibition of the iodide of potassium, and found lead only in the last one.

Dr. Mitscherlich failed to find any lead in the urine of animals which he had poisoned.

Other examinations of the urine have been made with equally irregular results.

From these observations it may be concluded that failure to detect lead in the urine in cases of lead poisoning has not, in many cases, been due to any fault in the method of examination, but to the fact that lead was not being eliminated by the kidneys. Lead is eliminated by the skin, the intestinal glands, the liver, and the kidneys. During the ingestion of lead it is often eliminated continuously by the kidneys, and can be detected in the urine. The presence in the urine, however, continues only for a few days after the metal has ceased to be taken into the system, though it may be found in the tissues for several months afterward.

The removal of lead from the tissues is hastened by the iodide of potassium. It is often assumed that the kidneys furnish the main channel of elimination in this case. The results of the examinations of the urine that have been made do not, however, confirm this view. It is probable that the chief channel of elimination differs in different cases. In some cases lead is eliminated mainly by the kidneys, in others by the intestinal glands and liver. If saturnine albuminuria is the result of efforts at elimination by the kidneys, lead should be found in the urine,

most frequently, in cases where the kidneys were undergoing degeneration. In the two cases reported in this paper no albuminuria existed.

MEDICAL PROGRESS.

Treatment of Whitlow and Sprains.—Dr. John Chiene, in his contributions to practical surgery (*Edinburgh Medical Journal*, June, 1886), writes as follows on the treatment of whitlow and sprains:

In deep-seated digital inflammations over the first and second phalanges, the cause is either an inflammation of the flexor sheath, or periosteal in origin. In inflammations over the anterior aspect of the terminal phalanx, the cause is periosteal, and the worst that can happen is necrosis of the terminal phalanx.

In all cases make your incision early, central, and in the long axis of the finger. Relieve tension, and prevent spread of the inflammation from the flexor sheath on the finger to the common flexor sheath on the anterior aspect of the wrist. In periosteal cases early incisions prevent necrosis of the affected phalanx. Whitlows are infective conditions, and are due to a colony of micrococci. The periosteal whitlows are cases of acute suppurative periostitis.

The infective character of these conditions must not mislead the surgeon into supposing that careful antiseptic precautions are unnecessary. Sepsis and infection are perfectly distinct conditions. Relieve the tension, and the evil effects of the pathogenic micrococci will soon subside; prevent sepsis caused by the entrance of septic organisms from the external air, and rapid healing will be the result. In patients who are liable to whitlows, as in people who suffer from boils and carbuncles, administer corrosive sublimate internally, it is a most powerful anti-fermentative.

In *Sprains*, carefully applied elastic pressure, with wadding, combined with massage and passive movement, gives the best results.

In diagnosticating an injury, look before you touch a limb. Remember the normal relations of the styloid processes in diagnosticating injuries in the region of the wrist; the relation of the head of the radius to the external condyle, the relation of the olecranon to the internal condyle of the humerus in the elbow-joint; and let the coracoid process and its relation to the head of the humerus be the principal guiding landmark in injuries of the region of the shoulder.

Always expose the uninjured corresponding region, examine it in the first instance, and let it be your standard (having satisfied yourself that it *is* normal) in diagnosticating the injury on the opposite side.

Effect of Subcutaneous Fractures on Body Temperature.—E. Müller has recorded the rectal temperature in 36 cases of uncomplicated fractures, and found, in opposition to the observations of Maas, a rise in temperature in 35. The maximum was usually reached on the first or second evening, and was maintained for from one to thirteen days. Neither the age of the patient, the amount of extravasation, nor the extent of the fracture appeared to influence the extent of the rise in temperature. Müller has collected all the records of uncomplicated fracture (English, German, and American) at the time available to him, and finds that out of 359 cases, 308—85 per cent.—passed through with marked rise of temperature.—*Centralblatt f. Chirurgie*, June 12, 1886.

Investigations on the Action of the Micrococci of Vaccine.—Dr. L. Voigt has presented an interesting study of vaccine cultures, an abstract of which follows:

Koch and Feiler, as the result of their researches, concluded that the microörganisms which are regularly found in vaccine lymph are pathogenic but do not contain the vaccine contagium, and that when isolated and used for vaccination neither produce a pock nor grant protection.

Quist, of Helsingfors, has grown vaccine lymph in various media and successfully vaccinated children with the products.

Bareggi has stated that the microörganisms of smallpox and vaccine are identical. He has described large and small cocci, which latter are probably the carriers of the contagion. They exhibit active Brownian movements, and develop so rapidly that in three days a kilogramme of artificial lymph may be prepared from a capillary tube of human lymph. With such cultures, six out of eight vaccinations were successful.

The author has separated and cultivated in gelatine three kinds of organisms which all liquefy the medium.

1. Small cocci which, near the surface of the gelatine, form grayish-white sharply defined spherical colonies, the periphery being of a pale yellow color. Under a high power they appear to possess a proper movement, and occur in knots of two and four. These are probably the carriers of the contagion.

2. Large cocci which form pale green spherical colonies with rough and indefinite surfaces, and under a high power show only slight Brownian movement. These were not always present.

3. Small cocci in gray, yellow, dark, sharply defined colonies with a delicate cloud in the neighborhood, presenting, under a high power, groups of two to four, but possessing no spontaneous movement. In stained preparations these are indistinguishable from (1), but are ineffective for vaccination. Three out of fourteen calves were successfully vaccinated with (1).

The author offers his results as a partial contribution to the subject, which requires further investigation.—*Manchester Medical Chronicle*, June, 1886.

Condition of the Urine an Aid to Diagnosis and Prognosis in Abdominal Diseases.—M. Thiriar, of Brussels, states that the amounts of urea and of chlorides in the urine furnish valuable information in abdominal surgery. When there is difficulty in determining whether an abdominal tumor is malignant or benign, the amount of urea is a very important aid. With Rommeläere he has always found that in the case of malignant tumors the amount of urea gradually diminishes till it stands at less than twelve grammes in twenty-four hours. The urine, of course, must be measured daily, a sample of the whole examined, and this frequently repeated, as a single observation is worthless. The patient must also be free from albuminuria and tuberculosis, and account must be taken of the food. In benign tumors of uterus and ovaries, the quantity varies between twenty-one and twenty-five grammes; in malignant tumors it is

below twelve. The same holds good of cancer in the intestines.

After operations in abdominal cases there is a close relation between the amount of chlorides and suppurative or destructive inflammation. When the quantity of chlorides falls below one gramme, suppuration is imminent. In all operations involving the peritoneum, an analysis of the chlorides may indicate whether the case is likely to recover.—*Glasgow Medical Journal*, July, 1886.

Influence of Pregnancy on the Circulation.—Engström, of Helsingfors, opposes the postulate of Spiegelberg, who assumes the existence of increased cardiac exertion in pregnancy, as conditioned by the increase both in the bulk of blood and area of circulation. Engström deduces from his own experiments and from those of Lahs, that the increment of the uterine circulation in nowise obstructs the blood-flow in the abdominal aorta, nor increases the work of the left ventricle. The clinically established fact that the left heart is more active in the latter months of pregnancy, he ascribes, not to the increased blood mass, but to increased intra-abdominal pressure—not due to direct pressure on the uterus or the aorta, but to a more or less great compression of all the abdominal vessels.—*Centralblatt f. Gynäkologie*, July 17, 1886.

The Kola Nut and its Action.—Watson Smith writes as follows to the *Manchester Medical Chronicle* for June, 1886.

The kola nut (cola acuminata) is indigenous to the West African coast. Heckel and Schlagdenhauffer say the seeds are reputed to clarify and render healthy the most foul waters, and even to make tainted meat edible. A member of the Linnæan Society gave, at a meeting of that Society, an account from actual experience of the kola, and of certain effects produced by it. He stated that the foreman of his estate was habituated to excess in drinking, and that every Saturday his habit got considerably the better of him. However, he had a wife who cared for him (and herself), and she reduced a kola nut to the condition of a paste every Monday morning shortly before her husband's services were required, and administered the paste to the man. In thirty minutes his head was clear again. But it is further maintained that after such an application of the kola a drunkard cannot return to alcoholic stimulants for some days without feeling nausea. At some of the garrison towns a native sits at the roadside, and sells the nuts as the soldiers pass. By the time the men reach the barracks they are quite clear headed, and the stupefaction caused by drinking spirits is gone. On the west coast of Africa, the Mohametans and Arabs surpass the natives in point of drinking capacity, for whilst drinking they also chew kola, and so anticipate the after ill-effects otherwise experienced, and prevent them. A little supply of kola nut, I would suggest, or its paste, might prove a useful help to the professional heads of our hydropathic establishments, serving for use as a kind of antiperiodic against those attacks of alcoholic craving, sometimes leading inmates to wander forth and commit themselves to positively dangerous excesses. The kola nut contains very considerable quantities of caffeine (over two per cent.), and also some theobromine, and it forms the basis of a stimulating food (the paste) of great value.

Dr. A. Hudson, Medical Inspector of the U. S. Navy, has recently stated, in a letter to Mr. Thomas Christy, of London, to whom he had applied for an experimental supply of the kola paste, that being put into possession, by the Surgeon-General of the U. S. Navy, of a sample of the paste, he had employed it in a case of mitral disease, with granular kidney of slow progress, the average quantity of urea contained in the urine being about half the normal. With much lassitude and malaise there were intense headaches (probably uræmic) at intervals of three or four weeks, and some dyspeptic symptoms. The kola was given economically for nearly a month, with apparently decided benefit. Certainly the tone and vigor of the patient improved, and the single headache which occurred within six weeks had less than a day's duration, and was of a mild character. Synchronously there was an increase in the amount of urea excreted, as well as in the quantity of urine.

On the Therapeutic Value of Preparations of Coca in Childhood.—Professor Pott, of Halle, records some experiments with coca. He used a tincture composed of one part of coca leaves to five parts of absolute alcohol, and an extract internally, and solution of the strength of five and ten per cent. of cocaine for subcutaneous injection and external application. He found the tincture, in doses of from five to twenty drops every hour or two hours, of the greatest benefit in the various forms of enteritis, gastroenteritis, colitis, and cholera nostras, in children under two years of age. Even in very severe and desperate cases, after from fifty to one hundred drops of the tincture had been taken—*i.e.*, within about twenty-four hours—the sickness stopped, the diarrhœa was greatly lessened, and a permanent improvement set in. Part of this improvement may have been due to the alcohol, and the ordinary rules for diet and hygiene were at the same time rigidly enforced. He found no benefit from its use in diseases of the respiratory tract or of the nervous system. The extract was not fully tried, but seemed of some use in the nervous attacks of older children. The chief novelty in his use of the cocaine solution was in its application in whooping-cough. He found that painting a five per cent. solution on the back of the throat three times a-day had an immediate and strikingly beneficial effect on the paroxysms, reducing them at once in number from twenty or more during the twenty-four hours to three or four, and is of opinion that the course of the disease may be shortened by some weeks by this method of treatment. He found the same application very useful in cases of inflammation of the tonsils and pharynx, and in various forms of angina.—*Edinburgh Medical Journal*, June, 1886.

Application for Use in the Eruption of Wisdom Teeth.—Delioux de Savignac has commended the following mixture as an application to the inflamed gums over wisdom teeth in the process of eruption:

Glycerole of starch	ʒij.
Pulverized borax	gr. xv.
Pulverized saffron	gr. viij.
Tincture of myrrh	gtt. x.

With this make gentle and repeated frictions of the gums.—*Revue de Thérapeutique*, July 15, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 14, 1886.

THE BRIGHTON MEETING OF THE BRITISH MEDICAL ASSOCIATION.

THIS week's meeting of the British Medical Association has a special interest to the profession of this country from the fact that the Association, for the first time in its history, has gone without its own borders and, ignoring geographical boundaries, has selected a representative of the American profession to deliver before it the annual Address in Medicine. The meeting has attracted an unusual number of American visitors, several of whom have contributed papers, and it affords another proof of the breadth of science and of the community of the English-speaking peoples.

We have the pleasure of laying before our readers, in another column, an account of the meeting, received by cable from our special correspondent at Brighton.

THE ADDRESS OF DR. BILLINGS.

A FEW months ago the Council of the British Medical Association invited Dr. Billings to make the Address in Medicine before the Association this year which was to have been delivered by the late Dr. Austin Flint, and in another column we have the pleasure of laying before our readers the full text of this Address, which, in every respect, was worthy of its author and the occasion. It has not only a present influence and usefulness, but it will do good in the future. Topics were appropriately considered which Dr. Billings was specially qualified to discuss, and they were presented with the clearness and accuracy which are characteristic of all his work.

The opportunity to present the real status of the American profession was offered, and it was well used. Such presentation was needed, and will be useful. Members of the British profession will better understand than they have hitherto the reasons for the differences in professional qualifications found in a country so vast as ours, with such varieties of population and manifestations of disease, and with numerous means of entrance into the profession: "over eighty gates, a number of turnstiles, and a good deal of the ground is unenclosed common."

The means which are being used to regulate the practice of medicine, especially in Alabama and in Illinois, were presented with commendation. But a point of great practical importance, which those physicians who are asking for legislation sometimes overlook, and which was presented by Dr. Billings, is that "all efficacious legislation must be substantially in accord with public opinion, since it is impossible to continue to punish for any length of time that which public opinion does not condemn; and as the great mass of the people of the United States have not as yet had such evidence as they can understand, and which would thoroughly convince them that it is to their interest to suppress quackery, it follows that it is necessary to go slowly and to allow such evidence to accumulate."

Very great improvement is undoubtedly being made in medical education, as Dr. Billings has so well shown, in those schools requiring preliminary examination and attendance upon lectures for three years. But, independently of this indication of advance, there are certain aspects of this question which medical teachers of a score or more of years gladly recognize. One is the improved qualifications of medical students. The number of those who enter upon the study of medicine after receiving a liberal education increases from year to year. Moreover, in many of those medical schools which do not require a three years' attendance upon lectures and a graded course, the number of students who voluntarily pursue such a course increases from year to year. It is only a question of time as to the adoption by all reputable schools of compulsory attendance upon a three years' graded course as one of the essential requisites for graduation.

One of the most encouraging facts in regard to the development of American medicine, Dr. Billings has presented in the generous gifts by wealthy persons, either for the establishment and endowment of a great hospital and school, as the Johns Hopkins, or for the endowment of special departments, as has recently been done for Bellevue, the College of Physicians and Surgeons, and the University of the City of New York. Such examples as have been set by Mr. Carnegie, the Vanderbilts, and the unknown founder of the Loomis Laboratory, will surely be imitated, and other of the great medical schools of the country will receive generous help.

The work of the United States government in founding a great medical library, the most valuable medical library for reference in the world, is briefly considered. It should never be forgotten that for this library, so vast, so useful, and so wisely selected, the American profession is under obligations chiefly to the zealous, wise, and faithful work of Dr. Billings.

THE TREATMENT OF SYPHILIS.

Fortunately for humanity the ravages of syphilis seem to be lessening. This is partly due to improved social conditions, and to greater vigilance on the part of those who have the supervision of soldiers, sailors, and the ignorant and degraded classes, who are the most fit subjects for destructive morbid processes. It is also partly due to better methods of treatment than were formerly in vogue. Fifty years ago the main thought in the treatment of syphilis seems to have been to meet a dangerous enemy in the most heroic way; and a careful study of the early writings on venereal diseases must leave the candid reader with the impression that much of the damage which was attributed to the syphilis ought to have been ascribed to its treatment. With the advent of men who did not think it beneath them to devote their lives to the study of venereal diseases alone, a better state of knowledge began to prevail. Before this, the patient was subjected to a conventional treatment, and if it did not fit him so much the worse for him. Now, the treatment is made to fit the patient, and under the influence of methods in which mercury took no part, it was found that syphilis might end in a cure, even if no medication was used. In this way it has come about that experienced syphilographers no longer teach the old doctrine of the incurability and ineradicability of syphilis, but can offer to their patients a good hope that they may be cured, and that they may beget offspring which shall be without their parents' taint.

The change from the older methods of treatment of syphilis has been gradual and progressive, and to-day it is as simple and sensible as formerly it was complicated and senseless. It has recently been the subject of discussion before the German Congress of Physicians. The sum of the views there expressed may be briefly stated as follows:

The treatment of syphilis should be begun as soon as the diagnosis is established. The best remedy is mercury administered by inunction. After the disappearance of specific symptoms the treatment may be discontinued, to be renewed only upon their reappearance; or, according to some authorities, it must be continued even in the absence of symptoms for a period of from two to four years. In this way syphilis can be cured.

In addition to these general assertions, there are a number of interesting details in regard to the treatment of syphilis which can be gathered from the discussion referred to. Excision of the initial lesion is regarded by a few syphilographers as capable of preventing general infection. Others regard the initial lesion as a sign of general infection. The former position is hard to establish, as it is open to two objections: First, that it is impossible for the diagnosis of the initial lesion to be certain until later manifestations appear; and, second, that it is impossible to be sure that the disease may not manifest itself long after the usual period of observation. This part of the treatment of syphilis cannot, therefore, be considered as yet accepted. Again, as to the proper time to begin constitutional treatment. Kaposi agrees with Hebra, Sigmund, and Zeissl that energetic treatment is harmful before secondary manifestations appear. Neisser believes in excision, and in beginning constitutional treatment as soon as the diagnosis is established, expecting this to diminish the intensity of the disease, but not to cut it short. He also shares the opinion of Fournier that the treatment should be continued for three or four years intermittently, using, alternately, large and moderate doses, in preference to uninterrupted small doses, of mercury. As to methods of administration, he sensibly says these must be adapted to the patient, and no one method applied to all indiscriminately. In the first outbreak, in case of relapse, or in anticipation of marriage or gestation, an energetic method is to be adopted; in the intervals, mild doses of mercury and iodide of potassium are to be used.

Von Ziemssen, of Munich, has found the hypodermatic method most convenient in hospital practice, but prefers inunction in private practice. Schuster, of Aix-la-Chapelle, declares that after an inunction course lasting from thirty to forty-five days, mercury continues to be excreted in the urine and feces for from six to eight months, and finds in this and in the fact that relapses are apt to occur at about this period, an argument for the renewal of the treatment. Ziemssen, of Wiesbaden, would continue the inunction course for months, and then discontinue it, considering the disease as cured until a relapse occurred. Leube has had thoroughly good results, during thirteen years of hospital practice, from adopting the plan of early constitutional treatment. Edlefsen, of Kiel, agrees with Leube as to the time to begin treatment, and considers inunction as the best method. He is afraid of large doses of the iodide of potassium, not as affecting the stomach, but as affecting the mucous membrane of the air passages. Bäumler advises the commencement of treatment as soon as the diagnosis is established. Doutrelepont is opposed to preventive constitutional treatment, and adopts the method of hypodermatic injections of sublimate solutions, as recommended by Lewin. Schumacher calls attention to the fact

that adopting the plan of long-continued intermittent treatment may prevent one's recognizing early cures of syphilis, and urges the importance of acting energetically in the presence of absolute lesions, and of withholding treatment in their absence. He advises a single repetition of the treatment after the lapse of a year, however, and another on the eve of marriage. Finally, Kaposi sums up the result of the discussion, which we have epitomized, as follows: 1. By general agreement the inunction method is the best in the treatment of syphilis. 2. There is no reason for inaction in the presence of syphilis; there are always means of successfully combating it.

If to these views we add our own, we shall only illustrate the fact that all syphilographers essentially agree with Kaposi. In regard to certain details, there is not perfect accord. It would, probably, be well to give due weight to the opinions of Schumacher, which we have cited, and to let our patients have a chance to show whether or not they were cured by the first treatment; for there can be no doubt that a large number can be so cured. The only objection to this plan is that late manifestations may declare themselves. But there is no good evidence that these are more apt to follow what seem to be early cures than those in which the treatment has been protracted. And it is certain that nothing can protect a patient against the diagnostic skill which attributes all sorts of obscure disorders to syphilis, whenever a previous venereal disease is confessed, and holds the relation to be all the more clear when such a disease is denied.

FECAL AMMONIA IN HEALTH AND DISEASE.

As a contribution to Treitz's theory of "ammoniæmia," which assumed the absorption from the intestine of ammonium carbonate, produced from the decomposition of urea, W. Brauneck has presented in the second volume of *Contributions from the Medical Clinic of Würzburg*, a very interesting series of observations. Tests were made of the feces of twenty-nine persons, including nephritics, cholera and typhoid patients, and healthy individuals. Omitting the details of the improved methods of analysis pursued, Brauneck's results may be summarized as follows: Under normal conditions the feces contain but little ammonia—about 0.15 per cent., while in typhus and cholera nostras its average amount in the dried mass is respectively 0.77 and 0.63 per cent. The dejecta of nephritics occupy a middle place in this regard, with a mean of 0.34 per cent. of fecal ammonia. It is a point of much interest, as demonstrating the fact that ammonium salts are absorbed in these cases, that the contents of the stomach and small intestine in these cases were found to contain more ammonia than did the contents of the large intestine.

THE MEETING OF THE BRITISH MEDICAL ASSOCIATION.

(*By Cable from our Special Correspondent.*)

Brighton, England, August 12, 1886.

The fifty-fourth annual meeting of the British Medical Association was opened in this city yesterday at three o'clock, in the magnificent Royal Pavilion, which was a favorite residence of George IV. in the latter part of the last century. The royal stables with their immense dome were years ago converted into a ballroom, and here the general sessions of the Association are held; the spacious apartments of the Pavilion itself being used for the Sectional meetings.

Over twelve hundred members participate in the proceedings, and a goodly contingent from America, twenty-five in number, is present. The weather is delightful, and the proverbial British hospitality is doing its full share in promoting the success of the meeting.

In the morning the Mayor of Brighton welcomed the Association by entertaining at luncheon, in the Royal Pavilion, the Council of the Association and some of the more distinguished visitors.

On Tuesday evening the President, Dr. Withers Moore, of Brighton, delivered the Presidential Address. He vigorously attacked the higher education of women and created surprise by citing American experience as strongly in support of his views. Speaking of the disastrous physical effects of higher education on American women, he quoted an eminent American authority as saying that: "If these causes should continue for the next half century to increase in the same ratio as they have for the last fifty years, it requires no prophet to foretell that the women who are to be mothers in our republic must be drawn from transatlantic homes." Dr. Moore further stated that there was scarcely an American physician who has specially treated the diseases of women who did not corroborate these words. The address was well received.

On Wednesday a meeting of the Council was held in the morning, and at 11 o'clock the second general meeting of the Association was held, at which the Address in Medicine was delivered by Dr. John S. Billings, of the United States Army. It elicited high encomiums, and at its conclusion Director-General Sir Thomas Crawford moved a cordial vote of thanks, which Dr. Ord, of London, seconded, and it was carried with applause.

In the afternoon the Association met in Sections. These were largely attended and the scientific papers which were read were of a high order of merit, and they generally elicited interesting and instructive discussion. In the evening the President held a brilliant *conversazione* in the Dome and Royal Pavilion, at which three thousand guests were present.

To-day the Address in Surgery was delivered in general meeting by Mr. Frederick Abell Humphrey, Surgeon to the Sussex County Hospital. The Association's

Gold Medal for Distinguished Merit—the highest honor which it is in the power of the Association to bestow—was then presented to Dr. Waters for his long and devoted labors on behalf of the cause of medical reform, which have been at length crowned with a large measure of success. This is the third time that the Association, in its history of over fifty years, has conferred this distinction. The Stewart Prize was subsequently conferred on Dr. Robert Cory for his valuable investigations of the dark problem connected with the practice of vaccination against smallpox, and the Middlemore Prize was awarded jointly to Mr. Berry and Mr. Adams Frost, whose essays stand in the first rank, and were found to be of equal merit.

The 1887 meeting of the International Medical Congress is an uppermost topic in private conversation, and the large delegation present from the American Medical Association is working industriously among the profession here to create a favorable impression concerning the prospects of the Washington meeting.

The Americans here will leave Brighton with most pleasant memories of their cordial reception, and of the scientific work of this year's meeting of the British Medical Association.

SOCIETY PROCEEDINGS.

THE AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-second Annual Meeting, held at the Pequot House, New London, Conn., July 21 and 22, 1886.

(Specially reported for THE MEDICAL NEWS.)

(Continued from page 137.)

WEDNESDAY, JULY 21.—FIRST DAY.

EVENING SESSION.

DR. J. A. ANDREWS, of New York, read a paper on

THE EFFECT OF THE ELECTRIC LIGHT UPON THE EYE.

In considering the relative effect of different forms of illumination, that obtained from gas, from kerosene, and from the incandescent light were studied. The electric light gives the maximum of light with the minimum of heat. So far, the only cases of injury to the eye from the electric light have resulted from exposure in close proximity to the arc light. In most of these cases the existence of previous eye trouble was not excluded. The effect in these cases can be best explained as occurring through the sympathetic nervous system rather than as a result of mechanical or chemical influences. It is not established that exposure to bright light can produce a diffused iritis. No case of injury to the eye from the incandescent light has been reported and out of eleven hundred workers with the electric incandescent light examined by the reader, there was not one complaint. Those suffering with errors of refraction claimed that the sight was improved. The light used was from twelve to sixteen candle power, and provided a shade to protect the eyes. The incandescent light possesses advantages which are wanting in other forms of artificial light, the principal of which are its steadiness and the fact that its use does not contaminate the atmosphere.

DR. C. R. AGNEW, of New York, stated that the incandescent electric light had been introduced into the Columbia College reading-room. All who have made use of it have expressed great satisfaction with it.

DR. W. F. MITTENDORF, of New York, said that the paper confirmed the results of his observations. The popular feeling has been against the electric light as injurious, but his experience proves the contrary. The light is so perfect that it need not be approached so close to the eye, and the efforts of accommodation are less. On account of its steadiness, less work is thrown upon the iris than with the flickering light of the gas.

DR. WILLIAM S. LITTLE, of Philadelphia, then described

A METHOD OF OVERCOMING DIPLOPIA WHEN PRISMS ARE NOT FULLY EFFECTIVE.

Double vision, especially in the lower field, is a source of danger in walking. This is the case, even where prisms are worn, as the patient, by not holding the head forward, may look under the spectacle and thus see double. A case of an elderly person with modified paresis of the superior oblique was described. This had led to two severe falls. A prism of six degrees, properly placed, united the double images below the horizontal plane. Above this plane objects were single. Myopia also existed in one eye, and required the combination of a sphero-cylinder with a prism for the right eye to correct the myopia and diplopia. In order to prevent looking under the glass and seeing double in the lower field, the speaker had resorted to the following procedure: the sphero-cylinder correcting the myopia of the right eye had been ground opaque for one-sixteenth of an inch above the horizontal plane, so as to obliterate sight in the lower field of vision in this eye. There has been attached to the lower portion of the frame the wire network used in protection glasses. This is carefully adjusted to fit close to the face, the perforations in the gauze having been stopped by painting. Vision is thus cut off below and under the spectacle. In this way, vision for the affected eye is only through the upper part of the myopic correction, and the necessity for a prism is done away with. The other eye has its myopic correction, and is the one in which vision in all parts of the field is clear. The right eye is used in only the upper part of the field, where no diplopia exists. This is better than entirely closing the affected eye by a ground glass, and is found more effective than with the prism, as danger of falling by seeing double is prevented. The same method may be applied to a diplopia in any position in the visual field.

The spectacles, as made by Borsch & Rommel, were exhibited.

DR. W. F. MITTENDORF, of New York, reported

TWO CASES OF MOLLUSCUM CONTAGIOSUM

which had come under his notice in asylums for children. In the spring of 1885 a little girl, having one or two small warts on the eyelid, was admitted to one of these institutions. In a few weeks other children exhibited similar growths on the eyelids, in some cases spreading to the lips and to the nose. Within three months after the admission of the first case, twenty-seven children were more or less disfigured by this affection.

In the second institution as many as forty children were affected at one time. Some of these children were sent to board with a farmer. One of twenty thus sent out had molluscum. In a short time the affection spread to over half of the children. It also attacked the child of the farmer and his wife. In a number of cases the tumors involved other portions of the face, but they were most marked on the lids.

As soon as attention was called to the condition, engetic treatment did away with it. Excision with scissors and touching the base with nitrate of silver proved most satisfactory. Simply pressing out of matter is more painful than excision. Unless excision is employed, the disease is apt to return.

Dr. Mittendorf also described a case of

MELANOTIC SARCOMA OF THE CONJUNCTIVA AND CORNEA.

Mrs. H., aged forty-six, came under observation August 22, 1884. In April of that year a black spot appeared upon the lower part of the conjunctiva and was removed. When she came under observation two other tumors had appeared. They were about the size and shape of cucumber seeds. Two or three spots, looking as though ink had been dropped on the eyeball, were also noted. The tumors were movable and the conjunctiva surrounding them slightly congested. Otherwise the eyeball was normal and vision almost perfect. The growths did not affect the left eye, which was highly astigmatic. The patient was a strong, hearty woman, with no appearance of cachexia. There had been no injury to the eye, and the family history was good. The preaural glands and those of the neck were not enlarged. The tumors were removed, and the wound in the conjunctiva brought together with sutures. Healing took place rapidly.

Four months later she returned with two growths starting from the lower portion and the outer canthus of the same eye. There was also a small flat growth on the cornea not connected with the tumors. The tumors were again removed and the patient returned to her home.

In the spring of 1886 she again made her appearance with the eye closed. There was a small tumor the size of a cherry which had developed at the seat of the former growth. The tumor, with a portion of the conjunctiva, was removed. A preaural gland and some glands in the neck were found slightly enlarged. The general health remained good. She had, in fact, gained in weight since the previous operation.

Four or five weeks ago she returned with another growth. The eyelids could not be separated. An incision was made and the tumor removed.

Microscopical examination showed the growth to be a sarcoma with round cells. The melanotic appearance was chiefly due to hemorrhage in the parenchyma. Pigment granules were also present.

Dr. H. D. Noyes, of New York, said that in a case of melanotic sarcoma on which he operated some years ago, the disease had not returned.

Dr. H. Knapp, of New York, had seen a number of these cases on which he had operated as carefully as possible, but they have all, after a variable period, relapsed.

Dr. O. F. Wadsworth, of Boston, referred to two cases of episcleral epithelioma which did not recur after operation.

Dr. B. E. Fryer, of Kansas City, read a paper on

THE USE OF HOT WATER IN SOME OF THE CORNEAL AND CONJUNCTIVAL INFLAMMATIONS.

In this plan of treatment, the water is used at as high a temperature as can be borne. After a few hours a temperature of 140° can be borne. The water should not be of a lower temperature than this, and as much higher as the patient can stand. A method of using it is by fomentation with a napkin dipped into the hot water and not wrung out and applied to the closed eyelids. This is continued for half an hour at a time and repeated every one, two, or three hours day and night. It may also be applied by suspending a vessel above the patient and allowing the water to escape through a tube, thus keeping up a continuous action of the hot water. In some cases, the temperature may be raised almost to the boiling point. During the intervals between the applications, a cloth wrung out of hot water is allowed to remain over the eyes. In some cases of purulent ophthalmia, the hot water may be thrown into the conjunctival sac.

In purulent conjunctivitis this application cuts short the attack more quickly and safely than the use of ice-cold water. In gonorrhœal ophthalmia, it quickly lessens the swelling and diminishes the occurrence of ulceration of the cornea. If ulceration has commenced, it is less likely to progress and the amount of cicatricial tissue is lessened. In these cases, he occasionally used instillations of sublimate solution and of finely powdered iodoform. This plan of treatment is not so readily applied in ophthalmic neonatorium. In catarrhal conjunctivitis and phlyctenular ophthalmia, it is a good adjuvant. In acute and chronic keratitis it is useful. Its most marked effects are seen in corneal ulcer. The small amount of opaque tissue left is astonishing. The pain and photophobia are also diminished by the hot water.

Dr. William F. Norris, of Philadelphia, had seen good results from the use of hot water in gonorrhœal ophthalmia, although he had not used it at a temperature higher than 120° or 125°. It is a comfortable application, and several apparently unfavorable cases have got well under its use.

Dr. Samuel Theobald, of Baltimore, said that he had not used hot water in purulent troubles, but in interstitial keratitis and specific keratitis its use had been beneficial. It favors absorption of the opacity of the cornea. Constitutional treatment and the use of atropia accompanied the applications of hot water.

Dr. William F. Norris, of Philadelphia, read a paper on

ASTHENOPIA, AND THE CHANGES IN REFRACTION IN ADOLESCENT AND ADULT EYES.

He first referred to the changes occurring in the shape of the eyeball at various periods of life. It is regarded by some as not necessary to correct slight errors of refraction, but the author considered their correction as of great importance when they produce asthenopia. By removing the trouble, the congestion and softening of the eye are removed and the lengthening of its visual axis is prevented. The congestion and softening were regarded as important factors in the production of astigmatism and conical cornea.

A number of cases of diminishing hypermetropia and

of hypermetropia passing into myopia, were described. Diminishing hypermetropia and increasing myopia are simply different stages in a process essentially the same. They are both the result of softening of the eyeball and slow distention in the direction of the visual axis. Careful correction in these cases is one of the best means of preventing their further progress. The eyes should be carefully measured under the influence of a mydriatic. The enforced rest of the eye, thus obtained, is an important aid in diminishing the congestion. During the dilatation of the pupil, dark glasses should be used, even in a mild light. All cases of hypermetropia, where there is a decided difference in level between the disk and the macula, should be carefully watched.

Dr. E. Gruening, of New York, referred particularly to a class of cases in which the patient on arising has pain in the eyes with photophobia, passing off in an hour or two, and is not able to fix on any object for any length of time. There is also lachrymation. When he finds such symptoms, he almost always finds evidence of nasal disease. The nasal reflex plays an important part in our modern pathology. All the affections due to nasal irritation are increased by the recumbent position, for this favors congestion of the erectile tissue of the nose. The speaker thought it improbable that eyes which have rested all night would manifest painful sensations, and this fact tends to exclude ordinary asthenopia in these cases. He has treated these patients by removing the nasal trouble; and in a series of 200 cases, 150 have been benefited, while the remaining 50 have passed from observation.

Thursday, July 22.—Second Day.

Morning Session.

Dr. S. Theobald, of Baltimore, presented a paper on

the amblyopia of squinting eyes: is it a determining cause or a consequence of the squint?

He criticised the views of Alfred Gräfe and Schweigger, that the amblyopia exhibited by squinting eyes is a congenital defect, and argued in favor of the older view that the amblyopia is secondary to the squint, and due to the mental suppression of the visual image formed in the squinting eye. He stated, in the first place, that it is a mistake to call this variety of amblyopia "amblyopia exanopsia," as the ambloypia is not due simply to want of use of the squinting eye, but to an active cerebral process which induces a much more rapid loss of vision. Schweigger and Alfred Gräfe, who both accept the theory of acquired retinal identity, believe that squint is often due to a non-establishment after birth of retinal identity. If this were the case, as there would be, from the first, no stimulus to binocular fixation, the squint ought to develop in early infancy, whereas it is rarely met with then, but usually makes its appearance about the fourth or fifth year. They both lay stress also upon the fact that some squinting eyes retain good vision for years, while others, which have squinted but a short time, are highly amblyopic, and that this contradicts the theory that the amblyopia is produced by the squint. These observations, however, do not conflict with the suppression theory, for as the amblyopia doubtless develops during the forming stage of the squint, it is reasonable to suppose that in some cases it will have reached a high grade by the time the squint is fully established; while, on the other hand, a marked difference in the refraction of the two eyes (because then the diplopia will be less annoying) will explain the retention of vision in the squinting eye.

The most convincing argument, however, in favor of the suppression theory, is that the peculiar regional characteristics which the amblyopia exhibits, are of just such a nature as we should anticipate if this hypothesis be the correct one, but entirely inexplicable if we suppose the amblyopia to be a congenital defect.

Until more convincing evidence is adduced to sustain the congenital amblyopia theory, it was suggested that we ought to act upon the older theory, that the squint produced the loss of vision, and so give our patients the benefit of an early operation for the correction of this deformity.

(The paper will appear in full in The Medical News at an early date.)

Dr. H. D. Noyes, of New York, differed from the conclusions presented in this paper. His objections were based upon an experience and careful observation for a number of years. It has been claimed that before the development of the squint such patients have had binocular vision. There is no proof of this, and the evidence is against it. Again, he had the records of a large number of cases of monocular amblyopia, presumably of congenital origin, without lesion demonstrable by the ophthalmoscope, which have had no squint, although they may or may not have had hypermetropia. Binocular fixation after operation is not infrequent; but, according to his experience, binocular vision is obtained in only one-fifth of the cases. It is rare to find material improvement in an amblyopic eye after operation.

Dr. O. F. Wadsworth, of Boston, agreed with the last speaker. A careful examination of this subject, ten years ago, convinced him that the amblyopia of squinting eyes is not due to disuse. At that time he had thought that he was alone in this view, but on looking up the literature of the subject, he found that Schweigger had said the same thing some years before. After operation, he thought that there is no decided improvement in vision. It is sometimes said that there is, but this is largely due to the fact that the vision is not carefully measured before the operation. He had never been able to increase the vision to any extent after operation.

Dr. George C. Harlan, of Philadelphia, said that it had been his experience that vision is not materially improved by operation. He had, at times, attempted to compel the patient to use the affected eye by keeping the fixing eye under the influence of atropia for a long time. In some cases, he had succeeded in improving the vision in the amblyopic eye. He related one case, in which the vision was increased from $\frac{20}{CC}$ to $\frac{20}{L}$. Some two years later this was still retained, the axis having become straight under the use of correcting glasses.

Dr. W. F. Mittendorf, of New York, remarked that where there is a central scotoma we cannot expect any improvement from an operation, but there are certain cases in which vision is at once improved. He had thought that this was to be explained by the removal of the undue pressure exerted by the internal and external

recti muscles, which is different from that exerted by the superior and inferior recti. Taking away this pressure puts the eye in a more favorable condition, and we should expect better vision.

Dr. Samuel Theobald, of Baltimore, regretted that Dr. Noyes was absent when the early part of his paper was read, for he had taken up the objections to which reference had been made. In regard to the restoration of binocular vision, his test has been as follows: If we cover the eye which formerly squinted, we find that there is still a balance of power in the internal rectus. If the amblyopia is not of too great a degree, the patient is directed to fix his eyes on a certain object. The squinting eye is then covered, and it at once turns in. When the covering is removed it again turns out, showing that it did so to obtain an image upon a corresponding point of the retina. He considered this conclusive evidence of the restoration of binocular vision. In regard to vision, he agreed that where there is a considerable amount of amblyopia, there is no appreciable improvement after operation; but this had no bearing upon the question whether the amblyopia is congenital or due to suppression.

(*To be concluded.*)

CORRESPONDENCE.

FARADIZATION IN EXTRA-UTERINE PREGNANCY.

To the Editor of The Medical News,

Sir: Will you allow me to make a brief reply to my friend Dr. Harris concerning the points which he discusses after reading my letter to the Obstetrical Society of Philadelphia, at its meeting on May 6th, reported in The Medical News of June 12, 1886.

1. Dr. Harris says that "this fœticidal method is a valuable method of saving women when in great danger of death from rupture of the fœtal cyst and internal hemorrhage." Dr. Harris evidently does not understand the pathology of these cases, because it is perfectly impossible to recognize them before rupture has taken place. In fact, women do not draw attention to their troubles in the pelvis until trouble arises, and as all extrauterine pregancies arise in the Fallopian tube, and as they give rise to no symptoms at all until rupture has taken place, when the onset of pain, exhaustion, and other symptoms, is sudden and violent, Dr. Harris's proposal of fœticide cannot be called into use until the danger has already become far advanced, and this danger can only be met by prompt abdominal section. To look upon it, therefore, as a method of preventing rupture is absolutely absurd, and cure of the rupture is only possible when the rupture has taken place.

2. Dr. Harris here again speaks as one without practical experience in such cases when he says that "we do not propose to act upon the fœtus after it has escaped into the abdominal cavity, unless the fœtus should be very small, and be easily accessible to the pole of the battery placed in the vagina." Dr. Harris knows little about the abdomen if he thinks he can determine when a fœtus has escaped from its cavity or when it has not, even when it is a fœtus at full term. Such a kind of proposal is very like searching for a needle in a truss of hay. He will easily see the force of this objection if he will kindly look at my records, now amounting to twenty-five operations, for extrauterine pregnancy at the time of rupture. In only two have I been able to find the fœtus, although in every case I have found the placenta. Finally, it is not the fœtus which is the source of danger but the torn placental vessels, and for them his galvanic needle would be a farce.

3. "Primary laparotomy," says Dr. Harris, "so far as we know of the operations, has been fatal in fifteen out of nineteen cases." Only one case out of my twenty-five died, and that was because it happened to be my first case, and I did not understand the operation; all the other cases have got well. This is a much better result than where the fœtus dies, or is killed and suppurates; and I do not think Dr. Harris mends his case much when he says that "the entrance of fœtal débris into the bladder is not necessarily fatal, as in the cases narrated by Mr. Tait, for Parry refers to nine cases, four of which recovered." It is not necessarily fatal, clearly, but it is nearly so as may be. Fifty-five per cent. mortality is high enough for me.

4. Dr. Harris says that "Mr. Tait appears not to be aware of the fact that cases of prolonged ectopic gestation have been comparatively numerous, as witness the following partial record," and he gives archæological extracts of twenty cases. Now, it is quite clear that Dr. Harris is far more of a scholar than a surgeon. Some of the cases that he quotes I was quite familiar with, but I have neither time nor inclination to trudge through musty old volumes for useless extracts. Prolonged ectopic gestation is of itself so extremely remarkable that its successful issue is likely, I think, to attract extraordinary attention, and we get assured therefore that every case which has come under observation has been published. But it is just here that the scholar gets wrong, and the surgeon keeps right. The surgeon knows that there are hundreds and thousands of these cases in which the gestation has not gone on to a successful issue, but has ended rapidly and with disaster, and these fatal cases are not published. I am sure of the first kind there is probably one to a hundred of the other which die disastrously, and are either not recognized, or not published if recognized.

I admire very much Dr. Harris's patient investigation of statistics, but I wish he possessed a little more of the ordinary surgical acumen.

Finally, let me say about this absurd proposal of electrolysis that it has already met with well-merited ridicule. A story came to me only yesterday from Buffalo, wherein an eminent specialist, who has repeatedly stated that he has had six successful cases of the electrolytic treatment of ectopic gestation, was made to discover that his sixth case was nothing of the kind, and that it never had been a case of ectopic gestation at all, and, therefore, there is abundant reason to suspect from this story that none of the other five were other than mistakes arising out of well-intentioned but misdirected enthusiasm.

The conclusion I arrive at about this proposed electrolysis is that, previous to rupture, cases of tubal pregnancy give rise to no symptoms, and, therefore, are not caught. When rupture takes place the danger is from hemorrhage, and that can be arrested only by tying the vessels of the tube and removing it. To try to stop this hemorrhage with galvanopuncture will be just as effectual as bathing the patient with tar water. When

the rupture takes place into the broad ligament (the only cases which go on to full term) we have no right to murder the child, seeing that both mother and child have been and can be saved by abdominal section.

I am, etc.,

Lawson Tait.

Birmingham, Eng., July 25, 1886.

NEWS ITEMS.

Lunacy in England.—The report of the Commissioners of Lunacy for 1885 shows that there are now 80,156 lunatics in Great Britain and Ireland, being a ratio to the population of 1 to 349. In the last year the number of lunatics has relatively decreased.

Dr. Breisky has succeeded Professor Späth, of Vienna, who has retired from the chair of obstetrics.

A Public Disinfection Institute has been opened in Berlin under governmental direction. There are chambers capable of completely disinfecting the clothes of two hundred families daily. All conceivable apparatus for thorough disinfection is provided.

Dr. R. P. Howard, having resigned the position of Vice-President of the International Medical Congress to be held in Washington next year, Dr. J. A. Grant, of Ottawa, has been appointed to the same office by the Executive Committee.

Surgeon General of the Army.—On August 6th, the President retired Surgeon-General Murray on age, and designated Chief Medical Purveyor J. H. Baxter, as Acting Surgeon-General.

Ether-tight Corks.—Corks may be rendered perfectly ether-tight by coating them with a solution prepared from four parts of gelatine, fifty-two parts of boiling water, and one part of ammonium bichromate (added to the filtered gelatine solution), and then exposing them for a few days to sunlight.

Leprosy.—Dr. George L. Fitch has for five years been in charge of the lepers in the Sandwich Islands. He gives it as his opinion, based on careful study and attempts to inoculate the virus into healthy persons, that leprosy is not a contagious disease.

Dr. William L. Dudley, late of Miami Medical College, Cincinnati, has accepted the Chair of Chemistry in Vanderbilt University, Nashville, Tenn.

Butter and its Substitutes.—Mr. J. E. Long, in a recent paper on the microscopic examination of butter, arrives at the conclusions that, "taking all things into consideration, we have no absolutely certain method of distinguishing between butter and some of its substitutes, and that of all methods proposed, the microscopic are perhaps the least reliable." These conclusions are similar to the ones reached by Prof. H. A. Webster, but are directly opposed to those of Dr. Taylor.

Cold and Putrefaction.—Recent researches by Messrs. Coleman and McKendrick, of England, on the effects of extreme cold on certain microbes, especially those concerned in putrefactive changes, show that the organisms are killed by exposure to a temperature of from 80° to 120° F. below zero, though their germs are unaffected, and speedily develop after an increase of temperature.

A Sanitary Convention at Big Rapids, Mich., under the auspices of the State Board of Health, will be held on Thursday and Friday, November 18 and 19, 1886.

International Professional Courtesies.—At the last meeting of the Sei-I-Kwai a vote of thanks was passed to Dr. H. C. Wood, of Philadelphia for the donation of 105 volumes of valuable medical works to the Tokyo Medical Library; a vote of thanks was also passed to Dr. Robert T. Wilson, of Baltimore, for the donation of nearly two hundred volumes, including a complete set of *Ziemssen's Cyclopædia*, to the Library.

The Case of Dr. Watson.—In a suit brought by the Society for the Prevention of Cruelty to Animals, of Jersey City, against Dr. Beriah A. Watson, a surgeon of eminence of that place, to recover damages for alleged cruelty to dogs in experimental surgery, Justice Lane gave judgment, July 20th, against Dr. Watson, and an appeal is to be taken to the Court of Common Pleas.

Mrs. Leland Stanford, wife of the millionaire Senator from California, has purchased a piece of land on Washington Avenue, Albany, adjoining the site of the old Lathrop mansion, and it is stated that on the whole property she will erect a handsome and well-appointed hospital for old men and women, as a memorial of her parents.

Organization of India Rubber.—M. Professor Van Lair, of Liège, announces to the Académie de Médecine the curious fact that a tube of caoutchouc placed between the two ends of a cut nerve becomes vascularized, the nerve-fibres prolong themselves into it, and finally the two ends of the nerve unite, the caoutchouc disappearing.

Culture of Vaccine in Mushroom Jelly.—Experiments have recently been made by the Finnish Medical Society in the cultivation of artificial lymph in sterilized mushroom jelly. The artificial lymph has also been dried and used for vaccination. A child was exhibited at one of the meetings who had been vaccinated by the artificial lymph in the arm. There were nine vesicles in three rows. They were all well developed, and did not present any dissimilarity, although two rows had been produced with lymph taken from different parts of the culture glass, and the third row with dried lymph from the same glass. Former experiments had not been so successful, owing to the resistance of the lymph to the effects of drying. The cultivation of the lymph has now been brought to a more satisfactory point.

How Far Can One See?—A discussion is going on in Europe concerning the distance at which large objects on the earth's surface may be visible. Emil Metzger mentions that he once saw, with some difficulty, Keizerspickt, in Sumatra, when distant 110 English miles; and he also made out Gug Merapi, in Java, when 180 miles away. From the Piz Muraun, near Dissentis, E. Hill has seen Mont Blanc, the intervening

space measuring about 110 miles. J. Starkie Gardner states that Mont Blanc is visible from the Piz Langard, though distant about three degrees. In Greenland, Mr. Whymper beheld a mountain from which he was separated by 150 miles; and from Marseilles, Zuch saw Mount Canigon at a distance of 158 miles. The whole range of the Swiss Alps has been looked upon by J. Hippisley while 200 miles away; while Sir W. Jones has affirmed that the Himalayas have appeared to view from the distance of 224 miles.

The Consumption of Tea.—The popular idea that the people of Great Britain consume more tea on an average per head of population than any other country in the world, is now shown to be erroneous. The Australian colonies and New Zealand (according to one of the Indian journals) drink far more tea per head of population than the British Islands. The Australians come first, with 7.66 pounds per head; the New Zealanders next, with 7.23 pounds per head; while the people of Great Britain, though appearing third in the list, consume only 4.90 pounds each. Newfoundland and Canada come next; while in the United States the consumption is only 1.30 pound per head; and in Russia, which is always regarded as a great tea-drinking country, the consumption is only 0.61 pound per head. Belgium, Sweden, Austria-Hungary, and Spain consume less than the other European nations; but there is not one nation on the Continent, with the exception of Holland, in which the annual consumption exceeds 1 pound per head. But in certain parts of the countries named, tea-drinking is much more common than in others. In certain Russian districts, especially, tea is drunk constantly and copiously; and it is this fact which has given rise to the notion that Russia is the most bibulous of all tea-drinking countries.

The Water-supply of European Capitals.—Rome heads the list, with her 204,000,000 litres of pure water every twenty-four hours. Her population being 345,036, every inhabitant can dispose of 591 litres per diem. London comes next, for every one of whose 4,085,080 inhabitants there are 300 litres daily. Paris takes the third place, her population amounting to 2,240,124, and each inhabitant having for alimentary uses 58 litres per diem, and for secondary purposes 169—a total of 227 litres. Berlin has 1,302,283 inhabitants, for each of whom there are 140 litres daily; Vienna 770,172 inhabitants, with 100 litres each per day; Naples 463,172, with 200 litres; and Turin 278,598, with 98 litres a head every twenty-four hours. A litre is a little more than 1¾ pint.

The American Otological Society and the Proposed Congress of Physicians and Surgeons.—At the annual meeting of the American Otological Society, held at New London, Conn., July 20, 1886, the following resolutions were adopted:

Resolved, That a Committee of *five* be appointed by this Society, which Committee shall be authorized to confer with members from other Medical Associations with regard to the organization of a convention or congress of such associations, said Committee to report at the next meeting of this Society.

Resolved, That it is the sense of this Society that nothing in this resolution shall be construed as implying the approval by this Society of any plan which shall involve the abandonment of its *independent* annual meetings at such time and place as it shall, from year to year, determine in accordance with its By-Laws.

Equine Relapsing Fever.—A very interesting report has been compiled by Veterinary Surgeon J. H. Steel, A.V.D., regarding a very fatal disease which broke out among transport mules in British Burmah toward the close of the years 1883 and 1884. The disease prevailed in the stations of Rangoon and Tounghoo, and carried off some 182 mules, representing a money loss of some 30,000 rupees. The fatalities at Tounghoo amounted to 50 per cent. of the total strength of the mules of the two infantry regiments, and at Rangoon the British Infantry Regiment lost one-quarter of its mules. These facts indicate the great importance of the disease as affecting the means of transport in war. Mr. Steel was specially deputed to investigate and treat the disease, and the report which he has prepared indicates great industry and acumen in collecting facts, and throws a flood of light on the nature and cause of the disease. Previous to Mr. Steel's inquiry, no definite conclusion had been arrived at on these points, and the fatalities were attributed to all sorts of conditions and causes. Mr. Steel set to work with thermometer and microscope, and showed that the disease was a true relapsing fever, probably resembling closely, although not absolutely identical with, the relapsing fever of man. Experiments proved the communicability of the disease by ingestion and inoculation to the dog, horse, mule, and monkey, and examination of the blood by the microscope revealed the existence of a parasite of the nature of a spirillum, very similar to the form found in the relapsing fever of man, and, like it, alternately appearing and disappearing during the relapses and intervals of the fever.

Obituary Record.—Dr. Frank Hastings Hamilton died at his home in New York City on Wednesday morning last. His illness dates from December, 1883, when he was attacked with pulmonary hemorrhage, due to fibroid phthisis. Malnutrition combined with the pulmonary trouble gradually undermined his vitality and for the last two weeks he was confined to his bed.

Dr. Hamilton was born on September 10, 1813, in the old village of Wilmington, Vt., and after an academic education was admitted to the sophomore class Union College, and was graduated in 1830. Shortly after taking his degree at Union he began studying medicine with Dr. John G. Morgan, of Auburn. During the winter of 1831–32 he attended a course of lectures at the College of Physicians and Surgeons of the Western District of the State of New York at Fairfield, Herkimer County, and in 1883 received a license to practise medicine and surgery from the Cayuga County Medical Society. After practising two years in Auburn he took the degree of M.D. at the University of Pennsylvania, and in the same year began a course of lectures on anatomy and surgery in his office in Auburn.

In 1839 Dr. Hamilton was chosen to fill a vacancy in the professorship of surgery at the college in Fairfield, and in August of the succeeding year was made professor of surgery in the Geneva Medical College. In 1844

he made a tour of Europe extending over a period of seven months, and published accounts of his travels in *The Buffalo Medical Journal* of that year. Upon his return to this country he made his home in Buffalo and was appointed surgeon to the Buffalo Hospital of the Sisters of Charity.

Upon the organization of the Buffalo Medical College, in 1846, he was made professor of surgery and held this position until November 28, 1858, when he accepted the professorship of the principles and practice of surgery in the Long Island College Hospital and removed to Brooklyn. In April, 1861, he became professor of military surgery, fractures, and dislocations, and professor of clinical surgery in the Bellevue Hospital Medical College. He remained in these positions until May, 1868, when, upon the resignation of Professor James R. Woods, he was made professor of the principles and practice of surgery, with operations, and continued in this capacity until March 15, 1875, when he resigned.

His first publication was a *Treatise on Strabismus*, printed in Buffalo, in 1844. In 1860 he published the first edition of his *Treatise on Fractures and Dislocations*. This work, which, when first published, contained but 748 pages, reached its seventh edition, containing 1001 pages, in 1884, and is the best known work on the subject in the English language. M. G. Poinsot, of Bordeaux, translated it into French, and a portion of it was translated into German. Dr. Hamilton's *General Treatise on Military Surgery*, the first edition of which was published in 1862, and the second in 1865, is said to be the only book on military surgery written in this country, excepting a small volume from the pen of a Confederate surgeon, published shortly after the war at Charleston. The *Surgical Memoirs of the War of the Rebellion*, in two volumes, were edited by Dr. Hamilton, and published in 1871 under the direction of the United States Sanitary Commission. The first edition of *The Principles and Practice of Surgery* was published in 1872, and the third edition, thoroughly revised, was issued early this year. Other works from his pen are: *Monograph on Fractures of the Patella*, *Health Aphorisms*, and *Medical Ethics*. In addition to these he prepared a number of papers on surgery, and was the inventor of twenty-seven surgical instruments, most of which are now in common use.

Dr. Hamilton's war record, and his professional relations to the case of President Garfield are well known.

Among his fellow practitioners Dr. Hamilton was always held in the highest regard and they availed themselves of every opportunity to show their respect for his abilities. In 1855 he was chosen president of the New York State Medical Society; in 1857 he was president of the Erie County Medical Society; in 1866 of the New York Pathological Society; in 1875 and 1876 of the New York Medico-Legal Society; in 1878 of the American Academy of Medicine; in 1878 and 1885 of the New York Society of Medical Jurisprudence; from 1880 to 1884 he was vice president of the New York Academy of Medicine, and in 1881 was made vice-president of the Woman's National Hospital. In 1868 he was made honorary associate member of the College of Physicians and Surgeons, and in 1869 the trustees of Union College conferred upon him the honorary degree of Doctor of Laws.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM AUGUST 3 TO AUGUST 9, 1886.

Wolverton, Wm. D., *Major and Surgeon.*—Granted one month's leave of absence, to commence on or about August 15, 1886.—*S. O. 104, Division of the Atlantic*, August 7, 1886.

Bentley, Edwin, *Major and Surgeon.*—Ordered from Department of Texas to the Department of the East.—*S. O. 179, A. G. O.*, August 4, 1886.

Appel, D. M., *Captain and Assistant Surgeon.*—Ordered from Department of the East to Department of Texas.—*S. O. 179, A. G. O.*, August 4, 1886.

Middleton, Passmore, *Major and Surgeon.*—Granted leave of absence until September 10, 1886.—*S. O. 100, Division of the Atlantic*, August 3, 1886.

White, R. H., *Captain and Assistant Surgeon.*—Ordered from Angel Island, California, to San Diego Barracks, California, relieving Captain and Assistant Surgeon Leonard V. Loring—*S. O. 64, Department of California*, July 28, 1886.

Loring, Leonard V., *Captain and Assistant Surgeon.*—Granted leave of absence for one month on surgeon's certificate of disability, with permission to apply for an extension of two months.—*S. O. 59, Division of the Pacific*, August 2, 1886.

Adair, Geo. W., *Captain and Assistant Surgeon.*—Ordered for duty as Post Surgeon at Fort Brady, Michigan.—*S. O. 103, Division of the Atlantic*, August 6, 1886.

Gandy, Chas. M., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for one months' extension.—*S. O. 103, Division of the Atlantic*, August 6, 1886.

Merrill, James C., *Captain and Assistant Surgeon.*—Assigned to duty as Post Surgeon at Fort Klamath, Oregon.—*S. O. 130, Department of Colorado*, July 30, 1886.

Beniam, Robert B., *Captain and Assistant Surgeon.*—Relieved from temporary duty at Fort Omaha, Nebraska, and ordered to Fort Bridger, Wyoming Territory.—*S. O. 97, Department of the Platte*, August 5, 1886.

RETIRED.

Murray, Robert, *Brigadier-General and Surgeon-General*, U. S. A., August 6, 1886.

APPOINTMENTS.

Harris, Henry S. T., to be Assistant Surgeon with the rank of First Lieutenant, January 5, 1886.

Wood, Leonard, to be Assistant Surgeon with the rank of First Lieutenant, January 5, 1886.

Banister, William B., to be Assistant Surgeon with the rank of First Lieutenant, January 26, 1886.

Mason, Charles F., to be Assistant Surgeon with the rank of First Lieutenant, May 5, 1886.

PROMOTIONS.

Bartholf, John H., *Captain and Assistant Surgeon.*—To be Surgeon with the rank of Major, January 4, 1886.—*Mem. A. G. O.*, August 2, 1886.

Kimball, James P., *Captain and Assistant Surgeon.*—To be Surgeon with the rank of Major, January 24, 1886.—*Mem. A. G. O.*, August 2, 1886.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING AUGUST 7, 1886.

Hutton, W. H. H., *Surgeon.*—To proceed to Key West, Florida, for temporary duty, August 7, 1886.

Bevan, A. D., *Assistant Surgeon.*—Ordered to examination for promotion, August, 1886.

Williams, L. L., *Assistant Surgeon.*—When relieved at Buffalo, New York, to proceed to Mobile, Alabama, for temporary duty, August 2, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 7, 1886.

Rush, Charles D., *Passed Assistant Surgeon.*—Detached from the Receiving Ship "Franklin," and ordered to the U. S. S. "Pinta."

Willson W. G. G., *Passed Assistant Surgeon.*—Detached from the U. S. S. "Pinta," ordered home, and wait orders.

ORIGINAL ARTICLES.

THE BACILLUS OF TYPHOID FEVER[1] (TYPHUS BACILLUS OF EBERTH).

BY GEORGE M. STERNBERG, M.D.,
MAJOR AND SURGEON U. S. A.

RECENT researches support the view that the bacillus described by Eberth,[2] in 1880, bears an etiological relation to typhoid fever—*typhus abdominalis* of German authors; and pathologists are disposed to accept this bacillus as the veritable "germ" of typhoid fever, notwithstanding the fact that the final proof that such is the case is still wanting.

This final proof would consist in the production in man or in one of the lower animals of the specific morbid phenomena which characterize the disease in question, by the introduction of pure cultures of the bacillus into the body of a healthy individual. Evidently it is impracticable to make the test upon man, and thus far we have no satisfactory evidence that any one of the lower animals is subject to the disease as it manifests itself in man. The recent experiments of Fränkel and Simmonds[3] show, however, that this bacillus is pathogenic for the mouse and the rabbit. We shall refer to the experiments of these authors later.

Before the publication of Eberth's first paper Koch had observed this bacillus in sections made from the spleen and liver of typhoid cases, and had made photomicrographs from these sections. His name is, therefore, frequently associated with that of Eberth as one of the discoverers of the typhoid bacillus. Other investigators had no doubt previously observed the same organism, but some of them had improperly described it as a micrococcus. Such a mistake is easily made when the examination is made with a low power; even with a moderately high power the closely crowded colonies look like masses of micrococci, and it is only by focussing carefully upon the scattered organisms on the outer margin of a colony that the oval or rod-like form can be recognized.

Several observers had noted the presence of microorganisms in the lesions of typhoid fever prior to the publication of Eberth's paper, and Browicz,[4] in 1875, and Fischel,[5] in 1878, had recognized the presence of oval organisms in the spleen which were probably identical with the bacillus of Eberth.

[5] Prager med. Wochenschrift, 1878, p. 33.

The characters which serve to distinguish this bacillus are given by Eisenberg[1] as follows:

"MORPHOLOGY.—Bacilli, three times as long as broad, with rounded ends, may grow to long threads—*scheinfäden*—and are also found as very short rods; are mobile, and probably possess flagella; take the aniline colors less intensely than most similar organisms.

"GROWTH.—*Upon gelatine plates:* superficial grayish-white colonies with serrated margins; under a low power these resemble glass-wool and have a brownish lustre. *Stick cultures in gelatine:* growth, for the most part, superficial in the form of a grayish-white layer with serrated margins; but little growth along the track of the needle. *Upon agar-agar:* superficial growth of a whitish color. *Upon potato:* invisible growth; after forty-eight hours the pieces of potato have a moist appearance; when the surface is disturbed with a platinum needle one receives the impression that it is covered with a cohering film; under the microscope this is found to consist of long spore-bearing threads of typhus bacilli. *Upon blood serum:* grows only along the track of the needle as a milk-white layer; grows slowly.

"SPORE-FORMATION.—At 32°–40° C. spores are formed in the course of three or four days; these are located at the ends of the rods. At 20° C. spores are formed after a longer period; at lower temperatures than this, spores are no longer formed."

The bacilli are best stained in sections by placing these for twenty to twenty-four hours in a solution of methyline-blue made by pouring a saturated alcoholic solution of this dye into water until it is of an intense blue color and quite opaque. The sections are washed out in water, not acidulated, then in alcohol, and finally in cedar oil, after which they are mounted in balsam. This is the method first recommended by Gaffky.[2] According to Eisenberg, the bacilli are not stained by Gram's method of double staining. A character which seems to be quite constant has been pointed out by Meyer, Friedländer, and others. This consists in the appearance of unstained portions of the bacillus which look like vacuoles in the interior or defects upon the margin of the rod. These unstained places have a circular or oval contour, and may be of one-half to three-fourths the diameter of the rod itself. They usually lie in the middle line, but may be upon the margin.

Of all the diagnostic characters given, the peculiar growth upon potato, first pointed out by Gaffky, is the most important. This serves to distinguish the typhoid bacillus from similar organisms which in their morphology and growth upon gelatine or upon agar-agar closely resemble it. The rods, as first pointed out by Eberth, have rounded ends, but this is by no means peculiar to the typhoid bacillus. They vary greatly in length, and while the prevailing form is that of a short rod three or

[1] Bakteriologische Diagnostik, Tab. 25.

[2] Zur Ætiologie des Abdominal Typhus, Mitth. a. d. k. Gesundheitsamte, Berlin, 1884, ii. 372–420.

four times as long as broad, filaments of considerable length are developed in cultures made in gelatine or upon potato. This is shown in Figure 1, in which, also, a certain number of rods containing spores have been drawn. The amplification in this figure is about 1200 diameters.

Fig. 1.

The researches of Gaffky, recorded in his paper referred to, strongly support the view that the bacillus under consideration bears a causal relation to typhoid fever. Eberth was only successful in finding the bacillus in the lymphatic glands or in the spleen in eighteen cases out of forty in which he searched for it. On the other hand, he failed to find it in eleven cases of various nature—partly infectious processes—and in thirteen cases of tuberculosis in which the lymphatic glands were involved, and in several of which there was ulceration of the mucous membrane of the intestine.

Koch,[1] independently of Eberth and before the publication of his first paper, had found the same bacillus in about half of the cases examined by him, and had pointed out the fact that they were located in the deeper parts of the intestinal mucous membrane, beyond the limits of necrotic changes, and also in the spleen, whereas the long, slender bacillus of Klebs[2] was found only in the necrosed portions of the intestinal mucous membrane.

The researches of W. Meyer[3] (1881) gave a larger proportion of successful results. This author confined his attention chiefly to the swollen plaques of Pyer and follicles of the intestine which had not yet undergone ulceration. The short bacillus which had been described by Eberth and by Koch, was found in sixteen out of twenty cases examined. The observations of this author are in accord with those of Eberth as to the presence of the bacillus in greater abundance in cases of typhoid which had proved fatal at an early date.

The fact that in these earlier researches the bacilli were not found in a considerable proportion of the cases examined, is by no means fatal to the view that they bear an etiological relation to the disease. As Gaffky says in his paper referred to:

"This circumstance admits of two explanations. Either in those cases in which the bacillus has been sought with negative results, they may have perished collectively, before the disease-process which they had induced had run its course, or the proof of the presence of bacilli was wanting only on account of the technical difficulties which attend the finding of isolated colonies."

[1] Mitth. a. d. k. Gesundheitsamte, Berlin, 1881, 1.
[2] Virchow's Archiv, 1881, Bd. 83.
[3] Inaug. Diss., Berlin, 1881.

Gaffky's own researches indicate that the latter explanation is the correct one.

In 28 cases examined by this author, characteristic colonies of the bacillus were found in all but two. In one of these, 146 sections from the spleen, liver, and kidney were examined, without finding a single colony, and in the other a like result attended the examination of 62 sections from the spleen and 21 sections from the liver. In the first of these cases, however, numerous colonies were found in recent ulcers of the intestinal mucous membrane, deeply located in that portion of the tissue which was still intact. These recent ulcers were in the neighborhood of old ulcers, and are supposed to have indicated a relapse of the specific process. In the second case the negative result is thought by Gaffky to have been not at all surprising, as the patient died at the end of the fourth week of sickness, not directly from the typhoid process, but as a result of perforation of the intestine.

Gaffky has further shown that in those cases in which colonies are not found in the spleen, or in which they are extremely rare, the presence of the bacillus may be demonstrated by cultivation; and that, when proper precautions are taken, pure cultures of the bacillus may always be obtained from the spleen of a typhoid case. Hein[1] has been able to demonstrate the presence of the bacillus, and to start pure cultures from material drawn from the spleen of a living patient by means of a hypodermatic syringe. Quite recently Philopowicz[2] has reported his success in obtaining cultures of the bacillus by the same method.

The fact that a failure to demonstrate the presence of microörganisms by a microscopic examination cannot be taken as proof of their absence from an organ, is well illustrated by a case (No. 18) in which the bacillus was obtained by Gaffky from the spleen and also from the liver, in pure cultures; whereas in cover-glass preparations made from the same spleen he failed to find a single rod, and more than 100 sections of the spleen were examined before he found a colony.

To obtain pure cultures from the spleen, Gaffky first carefully washes the organ with a solution of mercuric chloride—1:1000. A long incision is then made through the capsule with a knife sterilized by heat. A second incision is made in this with a second sterilized knife, and a third knife is used to make a still deeper incision in the same track. By this means the danger of conveying organisms from the surface to the interior of the organ is avoided. From the bottom of this incision a little of the soft splenic tissue is taken up on a sterilized platinum needle, and this is plunged into the solid culture medium, or drawn along the surface of the same, or added to liquefied gelatine and poured upon a glass plate. The colonies develop in an incubating oven in the course of twenty-four to forty-eight hours.

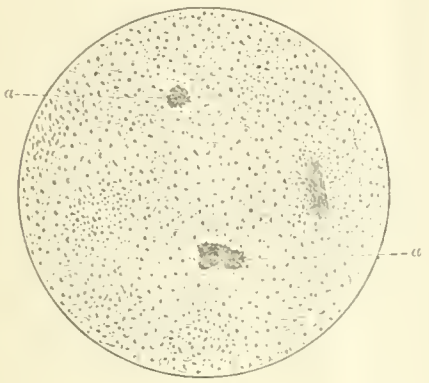
Gaffky has also shown that the bacillus is present in the liver, in the mesenteric glands, and, in a

[1] Centralblatt f. d. med. Wiss., Oct. 4, 1884.
[2] Wien. med. Blätt, 1886, Nos. 6 and 7.

certain proportion of cases at least, in the kidneys, in which it was found in three cases out of seven.

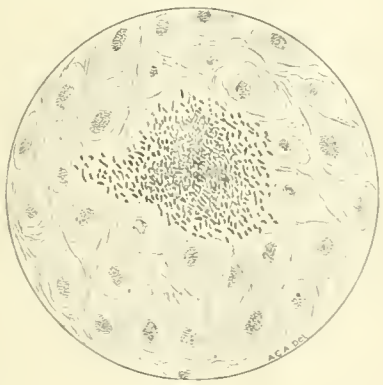
The appearance of the colonies in stained sections of the spleen is shown in Figs. 2 and 3. Two

FIG. 2.



colonies are seen in Fig. 2 (at *a*, *a*) as they appear under a low power—about 60 diameters. In Fig. 3 one of the colonies is seen more highly magnified—about 500 diameters.

FIG 3.



Fränkel and Simmonds[1] have recently demonstrated that the bacilli multiply in the spleen after death, and that numerous colonies may be found in portions of the organ which have been kept for twenty-four to forty-eight hours before they were placed in alcohol, when other pieces from the same spleen placed in alcohol soon after the death of the patient show but few colonies, or none at all.

This observation does not in any way weaken the evidence as to the etiological *rôle* of the bacillus, but simply shows that dead animal matter is a suitable nidus for the typhoid germ, a fact which has been repeatedly demonstrated by epidemiologists, and insisted upon by sanitarians.

The authors last referred to confirm Gaffky as regards the constant presence of the bacillus in the spleen. In twenty-nine cases they obtained it by plate cultures twenty-five times, and remark that in the four cases attended with a negative result, this result is not at all surprising, inasmuch as the typhoid process had terminated and death resulted from complications.

Gaffky did not succeed in obtaining cultures from the blood of typhoid fever patients, and concludes from his researches that if the bacilli are present in the circulating fluid it must be in very small numbers. He remarks that possibly the result would be different if the blood were drawn directly from a vein, instead of from the capillaries of the skin. Fränkel and Simmonds also report that gelatine, to which blood drawn from the forefinger of typical cases had been added, remained sterile when poured upon plates in the usual manner—Koch's method. The blood was obtained from six different individuals, all in an early stage of the disease—the second to the third week.

A similar experiment made with blood obtained, post-mortem, from the large veins or from the heart, also gave a negative result in every instance save one. In the exceptional case a single colony developed upon the plate. In view of these results we are inclined to attribute the successful attempts reported by some of the earlier experimenters (Letzerich,[1] Almquist,[2] Maragliano[3]) to accidental contamination and imperfect methods of research. The more recent work of Tayon[4] does not inspire any greater confidence. This author obtained cultures in bouillon by inoculating it with blood drawn from a typhoid patient, and found that these were fatal, *in a few hours*, to guinea-pigs, when injected into the peritoneal cavity. The lesions observed are said to have resembled those of typhoid fever—congestion and tumefaction of Peyer's plaques and of the mesenteric glands, congestion of the liver, the kidneys, etc.

The presence of the bacillus of Eberth in the alvine evacuations of typhoid patients has been demonstrated by Pfeiffer,[5] and by Fränkel and Simmonds.[6]

When Gaffky's research was made, Koch's admirable "plate method" for the separation of microorganisms contained in such material as feces, etc., had not been published, and this author did not succeed in demonstrating the presence of the bacillus in the intestinal contents. This demonstration is evidently not an easy matter, for while the bacilli are probably always present in some portion of the intestine during the progress of the disease, it does not follow that they are present in every portion of the intestinal contents. As only a very small amount of material is used in making plate cultures, and as there are at all times a multitude of bacteria of various species in the smallest portion of fecal matter, it is not to be expected that the typhoid bacillus will be found upon every plate. Fränkel and Simmonds made eleven attempts to obtain the bacillus by the plate method, using three plates each time, as is customary with those who adhere strictly to the directions of the master, and were successful in obtaining the bacillus in three

instances—in two in great numbers, and in the third in a very limited number of colonies.

The numerous attempts which have been made to communicate typhoid fever to the lower animals have given a negative result in every instance. Murchison, in 1867, fed typhoid fever discharges to swine, and Klein[1] has made numerous experiments of the same kind upon apes, dogs, cats, guinea-pigs, rabbits, and white mice, without result. Birch-Hirschfeld, in 1874, by feeding large quantities of typhoid stools to rabbits produced in some of them symptoms which in some respects resembled those of typhoid, but these experiments were repeated by Bahrdt[2] upon ten rabbits with an entirely negative result. Von Motschukoffsky[3] met with no better success in his attempts to induce the disease by injecting blood from typhoid patients into apes, rabbits, dogs, and cats. Walder[4] also experimented with fresh and with putrid discharges from typhoid patients and with blood taken from the body after death, feeding this material to calves, dogs, cats, rabbits, and fowls, without obtaining any positive results. Klebs[5] has also made numerous experiments of a similar nature, and in a single instance found in a rabbit, which died forty-seven hours after receiving a subcutaneous injection of a culture-fluid containing his "typhoid bacillus," pathological lesions resembling those of typhoid.

Eberth and Gaffky very properly decline to attach any importance to this solitary case, in which, as the first named writer remarks, a different explanation is possible and the possibility of an intestinal mycosis not typhoid in its nature must be considered.

Gaffky has also made numerous attempts to induce typhoid symptoms in animals by means of pure cultures of Eberth's bacillus, given with their food or injected into the peritoneal cavity or subcutaneously. The first experiments were made upon five Java apes. For a considerable time these animals were fed daily with pure cultures containing spores. The temperature of the animals was taken twice daily. The result was entirely negative. No better success attended the experiments upon rabbits (16), guinea-pigs (13), white rats (7), house mice (11), field mice (4), pigeons (2), one hen and a calf.

Cornil and Babes[6] report a similar negative result from pure cultures of the typhoid bacillus injected into the peritoneal cavity and into the duodenum in rabbits and guinea-pigs.

Quite recently Fränkel and Simmonds have made an extended series of experiments upon guinea-pigs, rabbits, and mice, and have shown that pure cultures of the bacillus of Eberth injected into the last mentioned animals—mice and rabbits—may induce death, and that the bacillus may again be obtained in pure cultures from their organs. It is not claimed that the animals suffer an attack of typhoid fever as the result of these injections, but that their death is due to the introduction into their bodies of the typhoid bacillus, and that this bacillus is thereby proved to be pathogenic.

The failure to produce the characteristic lesions of typhoid in the lower animals is evidently not opposed to the view that this bacillus is the specific cause of such lesions in man. Fränkel and Simmonds quote from Koch in support of this statement, as follows:

"In my opinion it is not at all necessary when we experiment upon animals to obtain precisely the same symptoms as in man. In support of this opinion, I may refer to the infectious diseases which we are able to induce experimentally in the lower animals. Anthrax runs a very different course in animals and in man; tuberculosis does not present itself in precisely the same manner in one species of animals as in another. Phthisis, as it occurs in man, we cannot, in general, produce in animals, and, nevertheless, we cannot assert that the animals experimented upon do not suffer from tuberculosis, and that the conclusions which we draw from such experiments are not perfectly correct."

In Fränkel and Simmonds's experiments a considerable quantity of material was used and the injections were, for the most part, made into the peritoneal cavity—in mice—or into the circulation through a vein—in rabbits. The influence of quantity of material used is especially shown in the case of the mice, and the question arises whether the pathogenic power of the bacillus for these animals does not depend upon the simultaneous injection of the ptomaine developed in cultures as a result of the vital activity of the organism. Thus we read that mouse No. 4 resisted an injection of a dilute solution of culture No. 1, but succumbed to a more concentrated solution, one-fifth of a Pravaz syringe. Mouse No. 5 was not killed by the injection of one-third of a syringeful of a dilute solution, but subsequently died from the injection of one-third of a syringeful of a concentrated solution. Mouse No. 16, injected October 10, with half of a syringeful of a very diluted culture, did not die. The injection was repeated on the 17th October with half a syringeful of a concentrated solution, with fatal result.

In all, thirty-five mice were injected, with a fatal result in twenty-seven cases. In rabbits the injections were commonly made in the large vein of the ear, and the quantity of material injected was considerably greater—from one-third the contents of a hypodermatic syringe to two syringefuls. In some instances death occurred within a few hours, in others on the following day or after an interval of two or three days. It is noticeable that the results differ very greatly as to the date of death and the relative quantity of material required to produce a fatal result. This probably depends to some extent upon the size of the animal, and perhaps partly upon individual differences in resisting power.

The experiments, considered together, show that the typhoid bacillus is not pathogenic for these animals in the same sense as is the anthrax bacillus or the bacillus of rabbit septicæmia. These organisms introduced beneath the skin or into the circulation in the smallest amount infallibly produce death, and

[6] Les Bactéries, Paris, 1885, p. 432.

at the expiration of a period of time which is tolerably uniform.

In all, seventy-nine experiments upon rabbits were made with the following result: Five injections into the intestine, five into the subcutaneous connective tissue, one into the lung, and two inhalation experiments, *all without result:* twenty injections into the peritoneal cavity furnished two, and forty-six injections into the vein of the ear, twenty positive results—*i. e.*, were fatal to the animal.

In the fatal cases the bacilli were proved to be present in the spleen by culture experiments and by microscopical examination of properly stained sections. The colonies are identical in appearance with those found in the spleen of cases of typhoid in man. The colonies were found in the spleens of the rabbits experimented upon, exactly as in the human subject, sometimes in the trabeculæ, sometimes in the Malpighian bodies, sometimes free in the splenic pulp.

Brieger[1] has recently made some very interesting researches with reference to the chemical substances which are produced as a result of the physiological processes attending the growth of this bacillus.

Having obtained a culture from the spleen of a typhoid patient, and assured himself by comparison with a pure culture given him by Dr. Koch that he was dealing with the right organism, Brieger planted the bacillus in a culture solution containing grape-sugar and salts—*Nährsalzen*—in which it thrived admirably. Such a solution at 30° C. became clouded at the end of twenty-four hours, and gave off an evident odor of ethyl alcohol, which increased from day to day. In addition to ethyl alcohol small quantities of the volatile fat acids were produced, among them acetic acid. Lactic acid was also formed from the grape-sugar. The bacillus grew still better in albuminous culture fluids. It did not in these give rise to the production of sulphuretted hydrogen or of any of the volatile products of putrefactive decomposition, such as indol and phenol. There was no gas-formation in such cultures, even after standing for eight weeks, but a slight odor, resembling that of whey, was given off from the cultures. Repeatedly, but not in every case, Brieger succeeded in obtaining from such cultures a very deliquescent basic product. This was obtained in only very small quantities, even when the cultures had remained in the incubating oven for a month. The physiological properties of this base have convinced Brieger that it is a new ptomaine. In guinea-pigs this ptomaine produced a slight flow of saliva and frequent respiration. Later the animals lost control of their extremities, and of the muscles of the trunk; they fell upon their side, but when placed upon their legs were able to move forward a little; they, however, soon fell again and remained helpless upon their side. The pupils gradually became widely dilated, and failed to respond to light; the flow of saliva became more profuse; no convulsions occurred. Little by little, the pulsations of the heart and the breathing became more frequent. During the entire course of these symptoms the animals had frequent liquid discharges. Death occurred in from twenty-four to forty-eight hours. Post-mortem examination showed the heart to be contracted in systole, the lungs to be hyperæmic, the intestine contracted and pale.

The experimental evidence which we have presented, considered in connection with established facts relating to the propagation of typhoid fever, seems to the writer to be convincing as regards the etiological *rôle* of this bacillus.

No other organism has been found, after the most careful search, in the deeper portions of the intestinal glands involved in this disease, or in the internal organs; on the other hand, this bacillus has been demonstrated to be constantly present. It is undoubtedly present during the lifetime of the patients; and is found in greater abundance in those cases which terminate fatally at an early date. It is not a putrefactive organism and is not developed in the tissues post-mortem, although it has been shown by Fränkel and Simmonds that it multiplies rapidly in the spleen after death, up to the time that putrefactive decomposition commences. This is quite in accord with what we should, *à priori*, have expected, in view of the facts relating to the propagation of typhoid fever. These facts indicate that the disease in question is due to a microorganism which is capable of multiplication external to the human body in a variety of organic media, at comparatively low temperatures, and that it is widely distributed. From the endemic prevalence of the disease over vast areas of the earth's surface, we may infer that it is induced by a hardy microorganism which forms spores. Eberth's bacillus complies with all of these conditions.

There are numerous facts which indicate that the development of an attack of typhoid and the severity of the symptoms depend to some extent upon the quantity of the infectious material introduced into the alimentary canal. Milk or water which has been infected directly by the discharges of typhoid patients is especially dangerous, and there is reason to believe that repeated or concentrated doses of such infectious material may be effective when a single draught of the contaminated fluid, or a greater degree of dilution, would be innocuous.

Again, we have evidence that the typhoid germs may become effective as a result of certain favorable circumstances relating to the individual or to his environment. Those agencies which reduce the vital resisting power of the tissues, and especially exposure to the emanations from putrefying material, to sewer gas, to vitiated air in overcrowded and illy ventilated apartments, etc., are recognized as favorable to the development of typhoid fever where the specific cause is present. All these facts seem to accord with the experimental evidence which indicates that the pathogenic power of the bacillus of Eberth depends upon the formation of a poisonous ptomaine rather than upon a special facility for multiplying in the tissues of a living animal. Indeed, it seems quite probable that its power to invade living animal tissues depends upon the toxic action of this ptomaine; or, it may be, of other ptomaines

[1] Weitere Untersuchungen über Ptomaine, Berlin, 1885.

produced under certain circumstances in the body in excess, or introduced from without. Such toxic agents may serve when the specific germ is introduced into the intestine in comparatively small numbers to give it the mastery over the vital resisting power of the tissues subject to invasion, and thus to induce an attack of the disease.

PRELIMINARY NOTES ON SOME OF THE PROPERTIES OF SODIUM FLUORIDE.

By LOUIS KOLIPINSKI, Pharm. D., M.D.,
Resident Physician, Children's Hospital, Washington, D. C.

The value of the alkaline iodides and bromides in practical medicine is so great that for some diseases and morbid phenomena they deserve the title specific. These compounds and their negative elements have, therefore, long been of general interest and the subjects of much special study. The chemical and physical properties of the halogen group arrange its constituents on a scale in which gaseous chlorine is first, liquid bromine second, and solid iodine last. Chlorine, the essential halogen of physiology, is the standard from which the medicinal importance of other members of the group may be judged, for the nearer they are to it in similarity of properties the less active may we hold them as drugs; nevertheless it is, *à priori*, to be supposed that any body ranking with this elementary group is possessed of some power over the human economy, how far this may be medicinal remaining to be determined.

Fluorine is usually classed with the halogens. Its chemistry in the free state has never been satisfactorily determined. Its inorganic combinations are of a definite character, and observations drawn from their effects are positive. It appears, therefore, that the lack of interest with which chemists have long contemplated this unmanageable body need not be transferred to the therapeutic experimenter. However strange it may seem, it is still, so far as I know, true that the fluorine compounds have been almost completely neglected, and with the exception of a few recent articles on hydrofluoric acid in disease, possess no literature in medicine. So far has this disregard extended that negative qualities have been assigned to this element. Thus Nothnagel and Rossbach,[1] in their work on materia medica, say: "Fluorine is without physiological or therapeutical importance."

Reflections like the above induced me to attempt some experiments with the view of becoming more familiar with this little known body and, if possible, to determine whether any of the inorganic fluorides could be made of use in therapeutics. Want of time and proper opportunities prevent me at present from presenting a more elaborate study, but in view of the many points of interest touched upon I desire to record in these preliminary notes some of the results obtained, especially as I would wish the whole subject to receive some consideration from those more competent than myself.

Sodium fluoride is described as crystallizing in white anhydrous cubes or octahedrons, soluble in twenty-five parts of cold water, not much more soluble in hot. Its solution attacks glass. It is insoluble in alcohol (and in glycerine). It has an alkaline reaction. The fluorides of sodium and of potassium have a great tendency to unite with HF and form acid fluorides, and consequently they readily give up half their metal to the weakest acids. One or two grains in an ounce of distilled water, with or without an alkaline carbonate, can be preserved for about two weeks with very little change.[1]

It possesses weak germicidal and stronger antiseptic powers. As a germicide it was not found to be active in less proportion than one to fifty, the method of Sternberg for determining the germicidal power of drugs being followed, with the exception of the hermetically sealed flasks. In place of these were substituted small test-tubes. The germs acted upon were those found in broken-down beef tea. It was found to be active as an antiseptic in the strength of one-tenth of one per cent. for clear beef decoction. An artificial culture fluid composed of tartrate of ammonium, sugar, and water, was preserved by 1 in 2733. The following experiment also illustrates this property. Three male adults were given one-eighth of a grain at 12 M., 11.55 A.M., and 12.02 P.M., respectively. Specimens of urine collected before and after the taking of the drug showed that that passed before rapidly grew turbid at the existing temperature, whilst that passed from one to two hours after remained clear during a period of seven days. That collected at the end of from three to four hours underwent the ordinary speedy decomposition. This shows that the fluoride is rapidly eliminated in the urine and that its preservative power is retained in that fluid.

A solution of two-tenths of one per cent. to which defibrinated blood is added prevents the development of germs or of any putrid odor. A solution of nine-tenths of one per cent. having an addition of one-sixteenth of its volume of defibrinated blood (rat, cat) preserved the red corpuscles for several days in their original form. On standing, the globules precipitate, the supernatant liquid being clear yellow. With a less percentage of fluoride the corpuscles become enlarged, though not globular, give out bud-like processes, and, finally, show a granular residue. In adding to the freshly defibrinated blood of an animal (rat) six to seven per cent. of the sodium salts of the halogens, the following is observed: The fluoride blood retains its scarlet

[1] Hdb. d. Arzeimittellehre, 5th ed., p. 259.

[1] The fluoride of sodium used was prepared in the pharmacy of the Children's Hospital, D. C. The method which I think preferable to follow, and one from which the product can be well preserved, is this: The hydrofluoric acid of commerce, which can be procured in small quantities, is added drop by drop to a not too strong solution of the acid carbonate of sodium. Care must be taken that the liquid do not at any time contain any free hydrofluoric acid. To the resulting watery solution of sodium fluoride alcohol is added in equal volume or excess; the precipitate is collected on a filter and dried. The product is in amorphous white crusts having on their under surfaces—next to the filter—a worm-eaten appearance. It can be preserved unchanged in any dry well-closed receptacle, even in a glass bottle. The commercial solution of HF often contains a trace of sulphuric acid from its manufacture, but so small in amount is the resulting sulphate that I have ignored it. In one sample of the salt prepared, no sulphuric acid was appreciable by chemical tests. The gutta-percha bottles in which hydrofluoric acid is kept can be well utilized as vessels for preparing the fluoride.

color. The blood to which the other salts have been added rapidly grows dark. On dilution with distilled water the fluoride liquid shows the turbidity of a fine precipitate. When the undiluted blood is evaporated on glass slides and examined under the microscope the red blood-corpuscles are seen enlarged, but of normal outline, in the presence of the fluoride—altered in various degrees and not distinctly recognizable in the others. This, of course, is observed after the blood has been kept for two or three days. By evaporation the fluoride blood forms microscopic crystals in the forms of crosses, daggers, or six-sided prisms radiating from a centre with their free ends bevelled. Spectroscopically, the blood shows the bands of oxyhæmoglobin. By exposure to the air methæmoglobin is developed.

The taste of the fluoride of sodium is alkaline and salty. When given in medicinal doses it is often noticed that the urine contains unchanged vesical epithelium and occasional cells from the pelvis of the kidney. I have not been able to practise any ready method by which its elimination can be quantitatively estimated, but that this occurs through the kidneys and very soon after absorption follows, I think, from the experiment on the urine recorded above. A saturated solution dropped upon the cornea and into the conjunctival sac of the eye of a dog results in no evidence of pain and no appearance of congestion or inflammation. Applied to the human skin its local action is also negative. Five grains, given to a dog upon meat, produce vomiting in a few minutes, which continues until the stomach is empty, and may then cease or end a little later with much retching and ejection of mucus. A similar quantity introduced into the rectum as an enema results in frequent seromucous discharges. The whole is accompanied with much tenesmus and rectal irritation. The gut is found hyperæmic or pale.

The injection of one or two grains into the subcutaneous cellular tissue and muscles produces symptoms of acute suffering.

A full-grown cat received two hypodermatic injections into the lumbar portion of the back. The respirations for a few minutes were much accelerated. Cries of distress, and savage biting at root of tail, and site of injection. Gnawed with cries of rage at anything presenting itself—a glass stopper, a hot steam-pipe. After an hour the animal is constantly moving about squeezing itself through any narrow space that can be found; six hours later it will not stir, refusing food and drink. This quiet stage continues for more than a day. About the punctures the connective tissue crepitates, the structures are moist from inflammatory effusion, and the muscular tissue is dark and softened.

The intravenous injection of a toxic dose (three grains for the cat) produces in this animal and in the dog, death in a few hours. The depth and force of the respiration are at once increased. The animal, if anæsthetized, rapidly regains consciousness, vomiting begins in a few minutes, and mucus hangs in strings from the mouth. With the vomiting may occur evacuation of feces and urine. At intervals there are movements of unrest with twitchings or tremors of the limbs. For the most part, the animal is quiet and unconscious. This stage begins with the cessation of vomiting, which ends within the first hour. The breathing in this second stage is slow and difficult; the head is held far back and the muscles of extraordinary inspiration inserted about the jaw act strongly. In its entirety it is the picture of the last moments of asphyxia continued for several hours, and may be disturbed by a transitory return of consciousness with efforts at locomotion. The heart continues to beat after the breathing ceases. Similar symptoms result from a large but not fatal dose (two grains for the cat). The animal revives in from six to eight hours. The urine in either case is slightly albuminous and rich in fluorine.

Non-fatal doses injected into the peritoneal sac or into the substance of the liver do not leave any evidences of inflammation after two or three days. Intraperitoneal and intrapleural injections are likewise fatal to the cat, even more rapidly than intravenous, pleural injections acting more rapidly than peritoneal.

Upon toads the action seems to be similar to that described as occurring in the cat and dog. The following experiment serves to show the general features observable:

2.40 P.M. Toad received one-fourth of a grain in eight minims of water through left side of abdomen.

2.50. Tries actively to escape.

2.55. Insp. 72; quiet; head low.

2.57. Tries to escape.

3.03. Active when disturbed; insp. 28.

3.08. Active when irritated; lies flat; legs drawn close to body; breathes at intervals; insp. 2–8.

3.15. Insp. 5; sides deeply receding in expiration.

3.20. No inspiration for a minute; active when irritated.

3.25. Breathes slowly at intervals.

3.25-28. Did not breathe; turned on back; active movements to escape.

3.30. Quiet.

3.40. Active when first touched; allows itself to be placed on its back; heart beating; no respiration; ineffectual efforts to regain normal position and then perfectly quiet as if dead; heart beats 48 with varying force; occasionally a few inspirations.

3.42. Regains first position.

3.45. Efforts to vomit; during intervals of full expansion of jaws they remain half open.

3.48. Jaws closed.

3.50. Moves feebly; does not stir when touched; no inspiration.

3.53. Efforts at vomiting.

3.55. Jaws slightly separated.

3.56. Dead.

4.00. Ventricle does not contract on irritation; auricles full of blood and actively contract when stimulated; twitching of toes; lower half of ventricle white and bloodless.

The clinical testing of this drug has been sufficiently extensive to deserve mention. It was chiefly administered in one of the outdoor medical services attached to this Hospital, during a period of six months. I will briefly mention those affections in which the record of cases shows some certainty, uniformity, and success in its use, and I will premise

by stating the manner in which it was prescribed. The fluoride can be given in aqueous solution or in papers, to be dissolved as needed. It is preferable that an equal proportion of the bicarbonate of sodium be added. When prescribed in the liquid form the total quantity should not exceed two fluidounces, as the power of a strong solution to attack glass forbids its being concentrated or long kept. The tendency of any quantity exceeding the fourth of a grain to produce nausea and vomiting, limits the dose tolerated by a child to this amount. The remedial doses used ranged from one-eighth to one-sixth of a grain, thrice daily. Complaint of slight gastric irritation was made by three different patients. It ceased on reducing the dose or directing it to be taken on an empty stomach.

The largest number of instances in which opportunity was offered for the use of the fluoride were cases of headache in children. Its effects proved quite uniform in most cases, and further showed that it was useless in one variety of this very common complaint. The following is a summary of the results:

1. An adult female received a fall striking the back of the head; a few days after, intense headache began of greatest intensity at the front and summit: the remedy failed to relieve her.

2. A boy of sixteen, whilst at play, was injured about the head; after two days occipital pain began: the result was as in the former case.

These two examples, which Day calls, in children, "cerebral headache," led me to conclude that the remedy possesses no value in the pain developing in the head after a jar or blow. I have not had opportunity to test the matter further.

Gastric or sympathetic headache, from errors in diet or sources of irritation in the intestines, were uniformly relieved by the exhibition of the fluoride.

1. A girl of eight had gastric indigestion with a frontal headache for two days: the pain in the head ceased, the other symptoms remaining.

2. A girl of five years had had headache for some time from constipation: relieved.

3. A boy of twelve, headache and umbilical pain for more than a week: pain in head relieved, that in abdomen remaining.

4. A boy of ten, continuous frontal headache: disappeared under fluoride.

5. A girl of eleven, headache from acute indigestion: relieved at once.

6. A girl of ten, umbilical pain and headache; had been treated for lumbricoid worms: headache cured.

7. A boy of seven, acute indigestion from improper food: headache relieved.

8. A girl of ten, headache for two weeks: relieved.

9. A boy of ten, umbilical pain and headache: latter relieved.

In children headache is often noticed as due to cough, especially when that expiratory effort arises from an irritation in the larynx, as in hyperæmia or catarrh of that part. This form was observed four times, each yielding promptly to the fluoride. A like success was obtained for the neuralgic and anæmic pains observed in girls and boys of nine to fourteen years, who, when debilitated from any cause, usually begin to suffer in this way from the strain of school-life. Five such cases were treated with uniform success; one of these, a girl of twelve, had suffered with paroxysms like migraine, and her state was such that all occupation had been relinquished, and her actions at times were so singular as to be considered irrational. Two of these five cases had a distinct malarial appearance and history.

The result of the treatment of intermittent and remittent fevers was very encouraging.

1. A boy of eleven, remittent fever: promptly arrested.

2. A girl of twelve, the same.

3. A girl of eleven, tertian intermittent fever: arrested in a week. Her attendance was irregular.

4. A girl of eleven, tertian intermittent: arrested at once.

5. A girl of thirteen, quotidian intermittent: arrested.

6. A child of two years, tertian intermittent, arrested at once. Returned after a week, again promptly arrested.

7. A boy of fifteen, quotidian intermittent for several weeks: improved at once. The intensity of the paroxysms reduced and disappearing on the the third day.

8. A boy of fourteen, appearance of malarial cachexia, had tertian intermittent fever six months before, regular paroxysms of headache: arrested at once. Reappeared on the fourth day of treatment for a single time, and then ceased.

Three cases of epilepsy major were treated for some months. They were all of the severest type, and all were approaching the stage of beginning dementia.

The first was a white lad of sixteen, who had formerly been treated in the Children's Hospital and had been discharged after remaining entirely free from any seizures for six months. Soon after his return home the fits reappeared with increased violence and frequency and for more than a year he made the rounds of private and charity treatment according to his father's means. When this boy came under observation he was having from six to twelve seizures a week. His mind was so dulled that ideation of the simplest kind was slow and laborious. A partial cerebral paralysis of the left side developed. Upon very large doses of potassium bromide he improved very much, so that he was free from any spells for a month. Thereupon sodium fluoride was substituted and the treatment continued for more than twelve weeks. Through this time he had an occasional fit at intervals of fifteen to twenty-one days. As described by him, the attacks were of slight intensity and with no after-effects of depression. He has been employed as a carpenter's apprentice, clerk, and so on, and both his parents and he are much pleased at this result. As he was not under constant control he could not receive the additional benefits of the avoidance of exciting causes, especially those from dietetic errors.

The second case was a negro boy of eighteen years. On first presentation he was a lamentable

object. Disheartened at all treatment, his guardian was desirous of placing him in some asylum, as he was a burden to others and helpless to earn his own support. Seizures were very frequent, and his face and head were covered with fresh bruises from the falls received at the period of onset. In the treatment by sodium fluoride he began at once to improve; pain and distressing sensations in the head disappeared, his countenance lost its epileptic look and became animated and intelligent. He was treated for about three months, during which time he had six or seven fits, very slight compared to those which occurred every few days before the drug was given.

The third, a white boy of twelve, was a case similar to the preceding one. Improvement began at once. This boy was likewise relieved of severe and frequent paroxysms of headache.

These are the most striking instances of epilepsy in which this remedy's effects were witnessed, and I would further remark that they were subjected to all the unfavorable circumstances which occur in a dispensary service. The distressing symptoms of bromism may be obviated by replacing at intervals the salt producing them by the fluoride.

In conclusion, I must return thanks to those who have aided me in different ways; to Dr. G. N. Acker, Visiting Physician to the Hospital, to my friends Drs. A. F. Hofer and R. R. Gurley, to Prof. E. T. Fristoe, of Columbian University, and to W. S. Thompson, Esq., of this city.

GONORRHŒAL TUBO-OVARIAN ABSCESS—RIGHT SIDE:

LAPAROTOMY; REMOVAL OF FALLOPIAN TUBE AND OVARY; RECOVERY.

By HOWARD A. KELLY, M.D.,
OF PHILADELPHIA.

The subject of this disease and operation is a German brunette of medium height, twenty-three years of age, and married for three years, but has never conceived. Her husband is of the same nationality, and at present is stout and hale-looking, but at the time of marriage was spare and delicate. Three years earlier he had an attack of gonorrhœa, of which he thought himself cured in three weeks, but just before marriage he was seized with orchitis which he thought due to a strain, and suffered with it for two weeks.

The present illness of Mrs. H. began two weeks after marriage at the first menstrual period, when she was suddenly seized with severe pain in the hypogastrium, and had to be carried to bed, where she lay in constant pain extending as high as the scrobiculus, accompanied by fever, vomiting, and excessive constipation. She felt "all sore inside as if she had caught a severe cold," and was two weeks confined to bed. She has had similar attacks at intervals ever since, obliging her to go to bed for several weeks, and one in the summer of 1885 was especially marked by great pain down the outside of the right thigh.

The first visit of Mrs. H. to me, was on March 31, 1886. She began to menstruate at fourteen, and has never missed a month since. The flow since her marriage has been increasing in amount, and for a year past has been at times excessive, lasting as long as two weeks. The odor has been foul. At the time of marriage she was spare in flesh, although she had been at one time quite stout; when I saw her she was sallow, pinched in expression, and of a cachectic hue. She had been five months under the care of a physician, who told her she had a fibroid tumor which was intimately connected with the side of her womb, and could not be removed without causing her death.

Examination.—A careful bimanual exploration, with due respect to the great tenderness upon deep pressure, showed that the uterus was upright in the pelvis, fixed, and forced to the left side by a mass which occupied the right of the pelvic cavity, and extended behind the organ. A very slight but distinctly perceptible movement of the uterus could be produced by pressure, the space on the left of the cervix being sufficient to admit the index finger. Douglas's pouch was filled by a growth feeling superficially hard, but not solid, and the side of the pelvis was not so packed but that a slight vertical motion could be effected; in sensation, the solidity of a fibroid was wanting.

The patient suffered excessively from constipation, and from the sensation of something being present in the rectum that could not be expelled by straining. She has sat upon a vessel for two and a half hours at a time, in the vain hope that the object might come away and relieve her distress.

April 5, 1886. By the careful use of daily enemata containing inspissated ox-gall, the whole bowel has been well cleaned out, and she seems generally improved by a tonic of quinine, ergotine, and monobromide of camphor. The mass in the pelvis has diminished, so that a nodular condition can be distinguished in the vagina instead of the uniform hard roof.

21st. By the faithful use of a hot douche, the uterus has become more free to move, and the abnormal mass can be felt to be limited to the right side of the pelvis.

28th. A remarkable change has occurred, the uterus lies left latero-flexed, its fundus behind the pubes an inch to the left, displaced by the globular tumor of the right broad ligament. This is a baggy mass extending from the displaced right corner to the pelvic wall and to the pelvic floor below. Its greatest diameter is upward, forward, and to the right.

May 1. Dr. R. P. Harris examined Mrs. H., by appointment in my office, the husband being present, and recommended to them that an early exploratory incision should be made, and, if found practicable, that the diseased growth should be removed. It was very evident to him that the health of the woman was breaking down, and required surgical relief. The next day her condition became more grave, and I decided to operate as early as practicable.

5th. The operation was undertaken, assisted by Drs. Jos. Hoffman and William A. Burns, and in the presence of Drs. R. P. Harris and Baldy, and Messrs. C. W. Sharpless and Henkle. Everything was abso-

lutely aseptic, no antiseptic of any kind was used; an abundant supply of pure water was constantly on hand. The bleeding from the skin and underlying tissues was unusually free. The intestines were of a deep dull red hue, with some lymph and spots of ecchymosis, exhibiting marked evidence of peritonitis. The uterus and tumor were found exactly as previously outlined. The first impression was that it would be impossible to remove the tumor without tearing out other pelvic contents, but encouraged by previous experiences, I slowly proceeded to wedge in my fingers between the tumor and pelvis, and then to separate the parts laterally, until by great care and tedious manipulation, the tumor was freed at all points but two, its broad ligament attachment and a firm adhesion to Douglas's pouch. In the latter situation, on attempting to elevate the mass, a small cyst broke, giving exit to perhaps a drachm of very fetid pus. This was immediately removed, and the operation completed with the greatest despatch consistent with safety. The pedicle was transfixed and tied, removing a long, thick Fallopian tube standing out like a ridge upon an ovary converted into a thick-walled cyst of about 2½ inches in diameter, and somewhat flattened, containing between two and three ounces of greenish, and very offensive fluid pus, which readily ran out when the tumor was incised after the operation had been completed.

To secure room for manipulation the intestines had been drawn out of the incision in the abdomen and wrapped in warm towels. I destroyed the whole pus-secreting surface on the pelvic floor by scraping it thoroughly with my finger and twisting a sponge into it, thus bringing up a quantity of shreds and puriform débris. The long nozzle of a syringe was then introduced, being first carried up under the liver, then over the kidneys, and then into the pelvis, carrying a stream of warm distilled water all over and among the viscera, which were also sponged over with fine sponges secured in long stem-handles. The protruding small intestine was also irrigated, sponged, wiped with fine sublimated towels, and then returned. These steps consumed much time, but were taken with elaborate care to secure perfect cleanliness.

The abdominal wound was now closed with shotted silkworm gut, four sutures to the inch. In making the final closure after all of the sutures had been introduced, it was discovered that a knuckle of small intestine had slipped down under some of the slack sutures, and had been included when they were finally drawn and shotted. This discovery, and the renewal of the sutures, saved the patient from what might have been a fatal attack of strangulation. The possibility of such an accident should be considered, when, for any cause, the flat sponge usually placed over the intestines has not been employed, as in this case, which was due to its having been infected by escaping pus. A glass drainage tube was carried down to the point from which the tumor had been enucleated, and before all the sutures were shotted, blood had welled up in it to the top. Great rigidity of the abdominal walls added much to the difficulties of every step.

The tumor removed was somewhat of the shape and size of the gizzard of a large turkey, and had the feel of a body containing a fluid. The Fallopian tube was closed at its uterine end, but much enlarged at its distal extremity which opened directly into the ovarian abscess, the fimbriæ being at one point quite perceptible upon the surface of the ovary. The whole mass was of the form of a short-beaked retort, with the beak brought in contact with the surface of the body of the retort and luted to it. The internal surface of the cyst was characteristic of old abscess cavities.

The notes of the recovery of the patient are briefly as follows.

6th. In much pain, pulse 146 at morning visit, and 160 when seen at midnight.

7th. A. M. Pulse 136; temp. 102°; no pain, no vomiting, tympanitic; drew off f℥ss pure blood from tube and changed the saturated dressings; P. M., pulse 120; temp. 102°; has taken a cup of milk and limewater during the day; dressings saturated with an ounce of black blood; less tympany; rests well; metrostaxis.

8th. Pulse 96; temp. normal; no flow from tube; no pain; metrostaxis continues.

9th. Pulse 76; temp. 98 8°; bowels moved slightly; complains of nothing but a foul taste; bowels well moved by enema, giving relief. The tube was removed, and on the next day six sutures were taken out, the remainder of the stitches were removed a week after the operation. In eight days she felt well, had a pulse of 80, and a good appetite, bowels regular

18th. Sitting up, is still thin and pale from her long illness, but feels well, is cheerful, has a ravenous appetite, and makes no complaint of any disability except her loss of strength.

Comments.—It is worthy of note that the first onset of the disease occurred at the next menstrual epoch after marriage, and it is probable that the virus then penetrated the ruptured follicle and established itself in the ovary in that way. It would be difficult to understand how an entrance through the capsule of the ovary could otherwise be effected, or why it should under other circumstances elect to penetrate the peritoneal coat of the ovary rather than that of some neighboring organ or tissue. Pyosalpinx is probably a step short of this stage, and represents an adhesive inflammation between ovary and tube in such a manner as to prevent the rupture of follicles into the dangerous area.

These cases of disease in the lesser pelvis, being confined almost or entirely below the pelvic brim, usually present great difficulties to the operator. The abdominal walls are often very fat, and owing to the fact that most of the patients have either never borne children or have for many years been sterile, the rigidity and inelastic condition of the muscles cannot be overcome. The difficulties of manipulating small structures bound down in the pelvis are at times vastly greater than in the most tedious ovariotomy. The pelvic adhesions are sometimes so intimate that portions of the structures are left behind, and in cases like the one under consideration, the most efficient drainage alone is but a dangerous and

unreliable way of attempting to prevent septic peritonitis.

I propose in future to meet these difficulties as follows: In the first place, where the abdominal walls are rigid and the intestines are being forced out so as to impede the view of the pelvis, I shall enlarge the incision as much as may be necessary, and turning out the intestines envelop them in an oil-silk bag on which hot cloths can be laid, and then proceed to examine the unobstructed pelvis. Scraping, followed by a thorough application of solution of the bichloride of mercury, and careful wiping out, will probably be the best plan for treating discharging areas.

Or again, where evidences of septicæmia arise within a few days after the operation, I shall reopen several inches of the wound and wash out freely the whole abdominal cavity with hot water. I had made every preparation to do this on the second day in the case of Mrs. H., but the remarkable improvement and fall of pulse rendered interference unnecessary.

113 E. Cumberland St., Phila.,
May 18, 1886.

HOSPITAL NOTES.

OBSTETRIC CLINIC OF PROF. SPAETH, VIENNA.

Service of Dr. Piskacek.

(Reported by E. P. Davis, M.D.)

The following interesting series of obstetric cases occurred recently in the clinic of Prof. Spaeth, during the service of Dr. Ludwig Piskacek, assistant.

Case I. *Placenta prævia totalis in a primipara; perforation of placenta by the accoucheur; spontaneous birth; recovery.*—Marie M., aged nineteen, admitted to the clinic March 2, 1886, at 2.30 P. M. Previous health good; her pregnancy had been without complications, no previous hemorrhage had occurred. First labor pains were felt at 4.30 A. M.; one hour later hemorrhage occurred.

On admission the internal examination revealed the cervix uteri obliterated, the os uteri permeable for two fingers; through the os uteri could be felt a spongy, easily bleeding body, the placenta. It was impossible by examination through the os uteri to determine whether the presenting part was the head or breech; the same was true of examination through the anterior vaginal vault. External examination showed the head over the entrance to the pelvis, the back on the left side, the breech in the fundus uteri, and the feet in the right upper portion of the uterus. Fœtal heart sounds could not be heard; the fœtus was thus in first position, the amount of amniotic fluid small, the head not freely movable. Labor pains increased in intensity and frequence.

As the os uteri was undilated and the patient was greatly weakened by the hemorrhage which had persisted during the forenoon, the vagina was tamponed with iodoform gauze, the patient's limbs were bandaged with flannel, two injections of ether were given and wine soup was administered. The radial pulse increased in strength and volume.

At 6.30 the tampons were removed and the os uteri admitted four fingers, and the head was slightly movable; the pains were strong, and it was resolved to perforate the placenta, and this was done; with the next pain the head became fixed in the pelvis and the hemorrhage abated; as some bleeding still persisted, three iodoform tampons were placed about the os uteri; with each pain the tampons were forced downward, and at 7 o'clock they were expelled from the vagina; with the following pain a dead female child, weighing 1600 grammes, was born.

To avoid post-partum hemorrhage, the placenta was quickly expelled by Credé's method; the vagina irrigated with a two and one-half per cent. solution of carbolic acid; an iodoform pencil was placed in the cervix, and the vagina tamponed with iodoform gauze. Immediately after delivery the uterus contracted well; but after a few moments it relaxed, and it was necessary to perform uterine massage for three hours to maintain contraction; the vaginal tampons were continued, and heat and stimulants freely used; patient's temperature 98.6° F.; pulse 140.

In the centre of the placenta was the opening through which the fœtus was expelled; the membranes were intact. On the day following the tampons were renewed, and a two and one-half per cent. carbolic acid douche again given.

Temperature in the morning 38° C.; in the evening 38.8° C.; pulse 120. Patient's general condition good.

March 4, A. M., temp. 99.3° F.; P. M. 102.6°; pulse 140.
5th, A. M., temp. 99.5° F.; P. M. 102.6°.
6th, A. M., temp. 100.4° F.; P. M. 103.6°.

Lochia profuse and bloody; on the extremities small reddish blebs which resembled the appearance of scurvy, also nose-bleed. Patient was given acids and chinoidin night and morning in half gramme doses.

7th, A. M., temp. 100.4° F.; pulse 116.
P. M., temp. 102.9°.

Patient was given ergot and chinoidin, half an ounce of sherry wine every hour; appetite remained good, and patient took solid food well.

8th, A. M., temp. 100.7° F.; P. M. 101.8°.
Right parametrium somewhat sensitive.
9th, A. M., temp. 99.7° F.; P. M. 102.2°.
10th, A. M., temp. 99.3° F.; P. M. 101.3°.
11th, A. M., temp. 99° F.; P. M. 102.6°.
12th, A. M., temp. 98.6° F.; P. M. 100.8°.
13th, A. M., temp. 98.6° F.; P. M. 100.8°.
14th, A. M., temp. 98.2° F.; P. M. 99.5°.
15th, A. M., temp. 96.8° F.; P. M. 99.5°.
16th, A. M., temp. 97.7° F.

Patient was able to leave her bed on the 15th; on the 19th, at the request of her father, she was discharged from the hospital.

Examination of blood on the sixteenth day after delivery showed forty per cent. of normal hæmoglobin; corpucles, 1,290,000 to cubic millimetre.

Case II. *Placenta prævia partialis in a primipara; long-continued hemorrhage; transverse position of fœtus; podalic version (Braxton Hicks) through os uteri admitting two fingers; extraction four hours later; recovery.*—Patient S. C., aged eighteen, was admitted on March 2d, at 7 P. M., having hemorrhage at the time of admission.

No authentic previous history could be obtained;

membranes had ruptured at 5 P. M., first pains were felt at 6. Immediately on admission an antiseptic douche was given, and three iodoform gauze tampons were introduced. As the hemorrhage was persisting in utero from the rupture of the membranes, and the patient was already very anæmic, two fingers were passed through the cervix, and podalic version was performed; the fœtus was brought down as a tampon for the true pelvis and lower uterine segment.

At 11 P. M. the os uteri was dilated sufficiently to permit the extraction of the fœtus without danger of lacerating the cervix; a dead child weighing 2100 grammes was delivered. In a quarter of an hour after the birth the placenta was expelled by Credé's method.

For three days after delivery the patient's temperature remained normal. In the evening of the third day an interne, acting without instructions, gave the patient an intrauterine douche; an hour later patient had a chill and temperature rose to 103.1° F.; pulse 140.

March 6, A. M., temp. 102.2°; pulse 120.
P. M., temp. 102.2°; pulse 140.

One-half gramme chinoidin three times daily. Parametrium sensitive on pressure; a laxative given.

7th, A. M., temp. 102.2° F.; pulse 120.
P. M., temp. 102.2° F.; pulse 120.

Chinoidin and cold compresses.

8th, A. M., temp. 101.2°; P. M. { temp. 102.2°. pulse 104.

9th, A. M., temp. 101°; P. M. 101°.

10th, A. M., temp. 99.9°; P. M. 100.4°.

11th, A. M., temp. 98.6°; P. M. 100.8°.

12th, A. M., temp. 97.6°; P. M. 98.6°.

13th, A. M., temp. 96.8°; P. M. 97.6°.

14th, A. M., temp. 97.2°.

Patient's appetite and general condition rapidly improved; she left her bed on the 14th; on the 17th she was discharged.

CASE III. *Placenta prævia totalis in a multipara; patient admitted in the highest degree anæmic; tamponing of vagina; spontaneous birth; normal lying-in period.*—Patient H. S., admitted March 11th in condition of extreme weakness. Stated that the present was her ninth pregnancy, previous confinements normal, her last child born five years before. Until a month previous, present pregnancy had been without complications. Four weeks before admission patient had a sudden hemorrhage at night without known cause, which ceased on assuming a recumbent posture. For three days before admission patient had been about, engaged in her usual vocations.

On the night of March 10th hemorrhage recurred, and the physician called ordered ergot and cold compresses without thoroughly examining his patient. Hemorrhage did not cease, and patient was therefore brought to the hospital at 10.30 A. M.

On admission, patient was exsanguine, no labor pains were present, she was conscious. The vagina was tamponed with iodoform gauze, and by this means the hemorrhage was checked. The limbs were enveloped in flannel bandages, hot cloths placed about the patient, and stimulants were given.

About 7 P. M., the patient having partially reacted, the tampons were removed, the vagina irrigated and digital examination revealed the os uteri permeable for only two fingers, the placenta covering the os with the exception of a small opening at one border; head presenting, the membranes intact. It was determined to rupture the membranes, and allow the head to descend. This was accordingly done, and with the descent of the head labor pains began. The vagina was again tamponed, and labor pains persisting forced the placenta into the vagina, and forced the head and body of the child past the placenta, and birth took place, the child having perished.

Collapse followed delivery, but the patient reacted well, and made an uninterrupted recovery; on the tenth day after delivery she was able to go to her home.

CASE IV. *Decapitation in a case of neglected shoulder presentation after efforts to perform podalic version had failed; extraction of the severed head with the James Simpson forceps; recovery.*—Patient, aged twenty-nine, was brought to the clinic by a midwife, at 9 P. M. March 9th, giving the following history: Married one year, the present her first pregnancy. The first indications of labor pains began on the evening of March 8th. At 4 A. M. March 9th, the membranes ruptured; a midwife was called who examined her patient about 11 A. M., and told her all was right; the pains gradually decreased, and ceased toward evening. At 7 P. M. a physician was called, who diagnosticated a transverse position, and tried for an hour to make podalic version. Failing in this Prof. Bandl was called, and he, not having the necessary assistants and conveniences for operating at the home of the patient, advised her to go to the clinic.

On admission, the patient, of more than ordinary stature, was pale, and exhausted. Measurements of the pelvis gave anterior superior spinous iliac 27 centimetres, cristæ iliac 31 centimetres, trochanters 32 centimetres, conjugata vera 10½ centimetres, conjugata externa 18 centimetres, periphery 87 centimetres. The vulvæ were œdematous; in the perineum a rupture. In the vagina was the left elbow of the child, very œdematous; the left shoulder was fixed in the entrance to the pelvis. The internal os uteri was so firmly contracted around the shoulder and neck, that from this fact, from the tetanic contraction of the uterus, and from the œdema of the shoulder, it was not possible to insert the hand in the uterus even during narcosis. In the cervix uteri were several fresh ruptures; patient's temp. 101.3° F., pulse 100. The child had been dead for eight hours.

When the ineffectual efforts at version and the serious condition of the patient were considered, it was determined to perform decapitation during narcosis. The fœtus lay in the first transverse position, head at the left side, abdomen above. Although the head was at the left, the left hand of the operator was inserted, grasping the neck; the right hand introduced the Braun's decapitation hook, and fixed it; traction was then made downward, and then the hook was elevated. A complete rotation of 360 degrees separated the vertebræ, and a second severed the neck completely. By traction on the prolapsed arm the trunk was then delivered; the hand was quickly introduced to deliver the head, and traction was made on the lower jaw, but owing to the somewhat contracted pelvis this was unsuccessful. In the critical condition of the patient it was necessary to bring the labor to an end at once, and the Simpson's forceps were applied, and the head delivered; the placenta was expelled soon after the delivery of the head. A douche

of 2½ per cent. of solution of carbolic acid was given, iodoform gauze was placed in the vagina; the rupture of the perineum was of moderate size, which the patient had sustained from the different manipulations, was closed with silk; the uterus contracted well without post-partum hemorrhage.

March 10, A. M., temp. 98.6° F.; pulse 96.
P. M., temp. 99.5° F.; pulse 84.

Tampons removed, and douche given, and fresh tampons inserted.

March 11, A. M., temp. 101.5° F.; pulse 108.
P. M., temp. 103.1° F.; pulse 128.

Treatment continued. Abdomen slightly sensitive; bladder paretic, requiring use of catheter.

March 12, A. M., temp. 101.5° F.; pulse 112.
P. M., temp. 103.5° F.; pulse 120.

Lochia somewhat foul; œdema at perineal stitches; sutures were removed, and the wound found overlaid with pus and gangrenous masses; a pseudo-diphtheritic exudate was present. The vagina and uterus were free from exudate; fragments of decidua were also expelled from the uterus.

March 13, A. M., temp. 102.6° F.; pulse 116.
P. M., temp. 103.6° F.; pulse 112.

Intrauterine douche of 2½ per cent. carbolic acid. Perineal and vaginal wounds were douched with solution of 1 : 1000 corrosive sublimate; over the wound surfaces was laid cotton saturated in sublimate solution 1 : 4000.

Patient's general condition good.

March 14. As symptoms of sublimate intoxication appeared, its use was discontinued.

A. M., temp. 101.8° F.; pulse 112.
P. M., temp. 103° F.; pulse 132.

Free douche with carbolic solution 2½ per cent., and the wound surfaces thoroughly painted with undiluted tincture of iodine. These applications and douches night and morning, comprised the antiseptic treatment of the case until its recovery.

March 15*th*, A. M., temp. 102.2° F.; pulse 120.
P. M., temp. 103.0° F.; pulse 120.
16*th*, A. M., temp. 98.6° F.; pulse 96.
P. M., temp. 102.8° F.; pulse 112.
17*th*, A. M., temp. 99.0° F.; pulse 88.
P. M., temp. 101.8° F.; pulse 108.

In the perineal wound islands of healthy granulations; uterus contracted well, was not sensitive; abdomen not distended, and not sensitive. For constipation, infusion of senna fol.

March 18*th*, A. M., temp. 98.6° F.; pulse 80.
P. M., temp. 100.4° F.; pulse 92.
19*th*, A. M., temp. 98.6° F.; pulse 76.
P. M., temp. 100.4° F.; pulse 80.
20*th*, A. M., temp. 97.7° F.; pulse 60.
P. M., temp. 99.5° F.; pulse 64.
21*st*, A. M., temp. 98.0° F.; pulse 60.
P. M., temp. 98.0° F.; pulse 64.
22*d*, A. M., temp. 97.8° F.; pulse 64.
P. M., temp. 99.2° F.; pulse 64.
23*d*, A. M., temp. 88.0° F.; pulse 60.

General treatment consisted of good food, and two large spoonfuls of sherry every hour.

When convalescent, patient was transferred to gynecological ward for closure of perineum; this was readily done, and complete recovery followed.

Case V. *Anatomical abnormality, namely, the opening of the rectum into the vagina, and the presence of only a pigmented spot at the place of the normal anus.*—Patient gave no history of previous injury, or confinement, which could have occasioned this condition, which was, she thought, congenital.

The opening of the bowel was a few centimetres above the posterior commissure. No well-marked sphincter was found, although the patient had never suffered from incontinence of feces. In size and appearance the abnormal anus was smaller and less well marked than a normal aperture.

She was delivered in Spaeth's Clinic under the following conditions: The pelvis was somewhat contracted, and the head failing to descend in the pelvis, the forceps were used. After delivery the patient suffered from diarrhœa, although every possible precaution was taken to insure cleanliness; she made a good recovery.

MEDICAL PROGRESS.

The Treatment of Hydrarthrosis of the Knee by the Methodical Application of Elastic Pressure.—Elastic compression alone exercises persistent action which produces favorable results. A very ingenious proceeding for keeping up continuous compression is that employed by Ruggi, of Boulogne. This surgeon treats hydrarthrosis of the knee by the constant application of a bag filled with shot: this exercises a uniform and permanent action, and produces very rapid absorption of the fluid. The advantage of this procedure consists in its exercising pressure without producing any strangulation, the pressure being applied to the anterior surface of the knee, leaving the other surfaces, especially the posterior, quite free. The only inconvenience attached to this method is the difficulty in maintaining the shot bag always in position. It also condemns the patient to a state of absolute immobility, in the recumbent position, during the whole length of the treatment. To obviate these drawbacks the author employs Esmarch's elastic bandage, and applies it in such a way as to overcome the objections to the ordinary methods of compression. A zinc gutter splint is applied to the back of the knee, and fixed by an ordinary bandage to the leg and thigh. Compression of the knee is now produced by the application of the elastic bandage, which embraces the posterior splint. The compressing force may be very considerable without interfering in any way with the circulation through the limb. The author cites some cases to illustrate his method, and in which he has obtained very satisfactory effects. Compression by the elastic bandage has been employed by English surgeons for many years in the treatment of joint effusions, also in the early stages of pulpy degeneration of the synovial membrane. The novelty of the modified plan suggested in this paper rests in the ingenious method adopted for preventing the bandage exercising undue and undesirable pressure on the vessels in the popliteal space, and to this end it

may, no doubt, be adopted with safety.—*Manchester Medical Chronicle*, July, 1886.

VINEGAR AS AN ANTISEPTIC.—ENGELMANN, of Kreuznach, has used vinegar in several cases of diphtheritis with very good results. He then tested its antiseptic properties by the usual methods, with unexpected results. He found vinegar to be more destructive to microörganisms than a 2½ per cent. solution of carbolic acid. The degrees of dilution for different methods of application were as follows:

For internal use	1 : 4.
As a gargle	1 : 2.
For spraying	1 : 2–3.
For application by the brush . .	Undiluted.

The author suggests the great desirability of further experiments in this regard.—*Centralbl. f. Gynäkologie*, July 17, 1886.

THE DIAGNOSIS OF SYPHILIS FOUNDED ON THE PERIOD OF INCUBATION.—DR. JOHN CHIENE presents the following practical suggestions regarding the diagnosis of syphilis:

If, after a suspicious connection, a period beyond ten days elapses before any local manifestation is evident, then the probability is that we have to deal with a case of syphilis. In such a case begin the mercury at once. In making your diagnosis do not be deluded by a local manifestation, either in the form of a gonorrhœa or a soft sore, either of which appears shortly after connection. The patient asks, "Have I syphilis?" How often is the answer given, "No," in one sense true—true of to-day, so far as any one can tell, but not necessarily true three weeks hence. Your answer should be, "I cannot tell; you *have* a gonorrhœa; you *have* a soft sore, but the time has not yet arrived to enable me to say that you *have not* syphilis. Six or eight weeks must elapse before I can speak with any certainty." The patient is not satisfied; this you cannot help.

Another snare to the unwary practitioner is that the patient always tends to blame the *last* connection. This connection is probably the cause of the gonorrhœa or soft sore, while the patient may have been inoculated previously with the syphilitic poison, which may at the time you see him be lying quiescent, and become evident at a subsequent date. At the end of the first week the gonorrhœa or soft sore becomes painfully evident; the average period of incubation in syphilis is three weeks; if two connections follow one another at an interval of less than a fortnight, it is evident that when the patient comes to you with the gonorrhœa or soft sore you cannot speak of his freedom from syphilis, which may show itself soon after the gonorrhœa, if caught from the first connection; if caught from the second connection, it may not show itself for a fortnight or three weeks after you are consulted.

The hard nodule, typical of syphilis—not a sore, not an ulcer, but an elevation, a local hypertrophy at the seat of inoculation—shows itself from ten days to eight weeks after connection. The average period of incubation is, in my experience, three weeks. This typical local hypertrophy may ulcerate if it is irritated in any way, but ulcerative destruction of tissue is an accident, not an essential of the primary lesion. This fact alone seems to me to go a great way in itself to show that the poison which causes a soft chancre—an ulcer—is different from the poison of syphilis. I cannot say how they were related in the past; I cannot say what may be their relations in the future. Neither an antiquarian nor a prophet, but simply dealing with the conditions as they come before the practical surgeon at the present time, I have no hesitation in saying that there are two distinct poisons—the one giving rise to a local ulcer, the other to a constitutional condition; the one probably more nearly allied to a putrefactive poison, the other to a truly infective poison; the one septic, the other pathogenic.—*Edinburgh Medical Journal*, June, 1886.

CURE OF BASEDOW'S DISEASE BY OPERATION.—PROF. HACK records in the *Deutsche medicinische Wochenschrift*, June 24, 1886, the following case. A girl of seventeen was suffering from Basedow's disease, with well-marked symptoms. The mucous membrane of the nose happening to be so much swollen that she had to keep her mouth almost constantly open, she came to Prof. Hack for relief. He cauterized the smaller mucous membrane on the right inferior turbinated bone, and found next day, to his astonishment, that the exophthalmos on the side operated on had almost disappeared. He operated on the other side, and anxiously awaited the result, which was also favorable, but not such a brilliant success as the first attempt. Strangely enough, the other symptoms likewise improved, and the operation on the nose seems to have cured Basedow's disease itself. Prof. Hack's explanation of the result is that the disease, in this case at least, was purely reflex, and that as soon as the irritation in the nose ceased the disease vanished. The increased action, and even the increased size of the heart, he attributes to the same reflex action; the coronary arteries might be dilated, and thus give the organ an over-plentiful supply of blood. He further upholds his reflex theory by giving parallel cases.—*Manchester Medical Chronicle*, August, 1886.

THE TREATMENT OF EPILEPSY.—ERLENMEYER recommends this mixture, as less disagreeable to the stomach and less likely to produce an eruption than the simple bromide.

Bromide of potassium . . .	4 grm.
Bromide of sodium	4 grm.
Bromide of ammonium . . .	2 grm.
Liq. amm. caust.	1 grm.
Aërated water	600 grm.

Half to one bottle a day.—*Annales de la Société médico-chirurgicale de Liége*, June, 1886.

NASAL INSUFFLATIONS OF QUININE IN PERTUSSIS.—BACHEM, of Bonn, records sixteen cases of whooping-cough, in which intranasal applications of quinine were employed with advantage, and resulted in cure, as a rule, within three weeks.

Quinine muriate is finely pulverized with one-third its weight of gum-arabic, and three grains of the mixture are twice or thrice daily insufflated in such wise that the entire dose is distributed throughout the nasal chambers.

The method in question was originally proposed by Binz, in 1868, and references to those other observers who confirm the claims made for the treatment, are given in the original.—*Centralblatt f. klin. Med.*, June 12, 1886.

Ligation of the Vertebral Arteries for the Relief or Cure of Epilepsy.—Dr. J. L. Gray, of Chicago, records three cases in which the method just indicated was advantageously pursued, and, basing his views on these and other records, presents the following conclusions:

1. Ligation of the vertebral arteries should take its place as a recognized procedure in the treatment of certain cases of epilepsy.

2. The operation should be confined to those cases in which the exciting causes of the attacks come from some region outside the brain.

3. The arteries should be tied as high up as practicable, and the ligature should include all the fibres of the sympathetic accompanying the vessel.

4. Where the side of the brain which is first invaded by the disease can be determined, the artery of that side should be ligated.

5. Where the invasion of the disease is apparently bilateral, both vertebrals should be ligated.

6. This operation should not be done as a substitute, but as an aid to other forms of treatment for the relief or cure of epilepsy.—*The Neurological Review*, July, 1886.

An Easy Method of Distinguishing the Solutions of Carbolic Acid used in Surgery.—Dr. Matthew Hay thus summarizes, in the *Lancet* for August 7, 1886, the means of obtaining the reactions indicated above.

The three reagents suggested are: 1. A saturated solution of chloride of sodium. This precipitates carbolic acid from solutions stronger than 4.8 to 5 per cent. at a temperature not exceeding 18° to 24° C. (64° to 75° F.). It causes no permanent precipitate in weaker solutions. 2. A carbolized saturated solution of carbolic acid. This precipitates carbolic acid from solutions stronger than 3½ per cent., and it does so, in the case of solutions above 4½ per cent., at any temperature below 32° to 35° C. (90° to 95° F.). It gives no permanent precipitate with weaker solutions. This is the best reagent for the simple distinction of the usual surgical solutions—2½ and 5 per cent. 3. Solid chloride of sodium. A small crystal of this precipitates carbolic acid from a saturated solution; whereas, when dissolved even to saturation in a weaker carbolic solution than 1 per cent., it gives no precipitate.

Cold Applications to the Præcordia in Fever.—Grigorovich presents the following conclusions regarding the effect of applying cold water to the region of the heart, based on a series of experimental observations made in the Rostoff military hospital:

1. The cold undoubtedly reaches the heart itself, and thus produces an effect on its action.

2. This effect is particularly noticeable when the cardiac beats are increased in frequency in consequence of a high temperature quickly attained, and where a certain degree of sensitiveness to a high temperature exists.

3. The effect of cold is not marked at the end of a prolonged attack of fever, pathological changes having by that time probably become established in the cardiac muscle.

4. The local application of cold is only capable of protecting the heart-muscle from the effects of a high temperature when it is applied assiduously from the commencement of the disease.

5. Under its influence the action of the heart improves, the number of beats diminishes, while their force and amplitude increase.

6. Cold applied to the region of the heart diminishes the gravity of the *typhoid* condition and favorably influences the respiration.

7. With regard to the effect of cold applied to the region of the heart on the course of the general temperature, Grigorovich cannot at present express a decided opinion, as he did not investigate the question; but in the results which he obtained, indications may be found of the possibility of its causing some diminution of the temperature.—*The Practitioner*, August, 1886.

Soft Chancre of the Middle Ear.—The *Gaseta Lekarska*, a Polish medical journal, contains a report by Dr. Guranowski of a case of soft chancre of the middle ear. The patient was a woman with a phagedænic chancre of the genitals, who, from snuffing tobacco, managed to introduce the virus into the nose, where the septum had become ulcerated, with copious discharge of the foul pus. From this the infective material must have passed through the Eustachian tube into the middle ear. Deafness and pain were complained of, and subsequently perforation of the tympanic membrane occurred, a large quantity of purulent matter being discharged through the opening and infecting in its turn the external meatus. The case was treated by the introduction of iodoform into the ear and nose, and by injecting warm water through the ear by means of the Eustachian catheter. In a month's time the patient regained her power of hearing and completely recovered. Dr. Guranowski has a great belief in the efficacy of washing the middle ear with warm water, having seen cases of severe inflammation recover under this treatment where it was feared that the only hope of saving the patient's life lay in trephining the mastoid process.—*The Lancet*, August 7, 1886.

Kauri Gum as a Medicinal Substance.—Many years ago Dr. Hammond, of Bournemouth, presented me with a fine specimen of Kauri gum, which one of his sons had brought from Auckland, in New Zealand. In experimenting with the gum thus supplied I have found that it may be made to perform many useful services in medicine. When the gum is burned—and it burns briskly—it gives out a very pleasant odor which destroys the odor of putrefying organic substances most effectively. Dissolved in spirit it makes a fluid which burns in the lamp with good effect. Reduced to a fine powder and shaken with water, it communicates to the water new properties, so that sprayed in a room it renders the air ozonic. It mixes well with ointments, forms a good combination with soap, and combined with iodine is a useful deodorizer and disinfectant. The gum is from a pine, the Kauri tree, *Dammara australis*. —Dr. B. W. Richardson, in the *Asclepiad*, July, 1886.

Gaseous Medication per Rectum.—The ingestion of gaseous medicines by the lower bowel was the subject of a recent communication by M. L. Bergeon to the Paris Academy of Sciences (*Comptes Rendus*, July

12th). His research has extended to a variety of diseases, but for the present he only records his experience in the treatment of pulmonary phthisis. After having tried a variety of balsamic substances of parasiticide or antiseptic repute, M. Bergeon gave the preference to sulphurous mineral waters (Eaux Bonnes, Challes, etc.). A current of from four to five litres of carbonic acid gas traversing from 250 to 500 grammes of sulphurous mineral water was introduced per rectum twice in the twenty-four hours. After a few days' use, cough was notably diminished and almost suppressed, the expectoration greatly modified in quality and quantity, the sweating stopped, and the general state improved; and that not only in incipient, but also in confirmed phthisis. Daily auscultation established the disappearance of moist râles.—*The Lancet*, August 7, 1886.

Conditions which Aggravate Syphilis.—Fournier maintains that the gravity of syphilis depends not so much upon the quality of the syphilitic virus as upon certain physical conditions existing in the infected individual. These conditions he discusses as follows:

1. Alcoholism. A powerful factor in increasing the virulence of this affection, favoring the spreading and increasing the intensity of the cutaneous lesions; producing severe symptoms, tertiary in character, early in the secondary stage of the disease; creating special types of eruptions, malignant, and involving large areas of the skin surface, causing more frequent outbreaks of the syphilides, depressing the system and sometimes determining a cachexia, which brings on death at times, and finally predisposing to early nervous manifestations and causing deposits in the brain and spinal marrow.

2. Age. Syphilis is always severe at the two extremes of life. In the infant the disease, whether inherited, congenital, or acquired, is very frequently fatal, this being in strong contrast with its benignity in the child, two, five, or six years of age. In the adult it is usually mild. After fifty or fifty-five years the disease begins to be severe, and in old age it is extremely virulent, the chancre having a tendency to become large and phagedenic, the syphilides ulcerating easily, tertiary symptoms, gummata, and cerebral syphilis showing themselves early.

3. Scrofula and tuberculosis act on syphilis and give rise to special symptoms, and at the same time syphilis exerts an unfavorable influence on those diseases. In those cases the syphilides have a moist, suppurating, and fistulous character; ocular, osseous, and articular lesions are frequently present; and the larynx, pharnyx, and nose are early and deeply involved. In scrofulous subjects a particular, mixed kind of inflammation of the glands is noticed and in young subjects lupus is common. In patients with a tuberculous tendency pulmonary lesions are very often hastened.

4. Malaria also predisposes to grave forms of syphilis, as is known to all those who have had the opportunity of following the latter affection in persons affected with malarial toxæmia.

5. All the agents which depress the vital economy can serve as factors of virulence in syphilis, such, for instance, as extreme poverty, bad hygiene, insufficient alimentation, previous or accompanying disease, pregnancy, prolonged lactation, fatigue, mental worry, etc.; the most common, and, therefore, the most important of these being extreme poverty.—*New Orleans Medical and Surgical Journal*, August, 1886.

Iodoform Poisoning.—In an article thus entitled in the *Boston Medical and Surgical Journal*, of August 5, 1886, Dr. E. G. Cutler presents a very full bibliography of the condition in question, together with the following conclusions:

1. Fresh wounds or unhealthy or tuberculous surfaces are the only ones fitted for the application of iodoform.

2. Only a thin layer or small amount of iodoform is to be applied.

3. When granulations appear healthy, iodoform should be omitted and some other non-poisonous substance substituted.

4. At the first symptom of poisoning, or coincidently with the original use of it, compounds of the alkalies and vegetable acids are to be given by the mouth at frequent intervals, as acetate of potash. If severe symptoms supervene, transfusion with common salt solution is to be resorted to, and the wound is to be washed free from iodoform with pure water and an alkaline carbonate solution and afterward powdered magnesia is to be dusted on.

The Pathogenesis of the Essential Anæmias.—Silbermann presents the following conclusions from an elaborate experimental investigation: 1. Progressive pernicious anæmia is induced by an increased and abnormal destruction of red and white corpuscles and by defective blood regeneration. 2. Pernicious anæmia is essentially a hæmoglobinæmia. 3. The blood in pernicious anæmia is exceptionally rich in fibrin ferment, and is thereby dangerous to the organism. 4. The frequent dermal, mucous, and retinal extravasations in this disease are due to capillary emboli or to capillary stasis. 5. The anæmic fever is of humoral origin and is conditioned by the large proportion of ferment in the blood. 6. The intermittent character of the fever corresponds with the changing phases of the blood destruction. 7. The large, fatty deposits sometimes observed in pernicious anæmia are not conditioned alone by the diminution in tissue respiration caused by decrease in hæmoglobin, but chiefly by an abnormal distribution of blood, consisting in a very considerable venous stasis and arterial anæmia. 8. In animals the gradual introduction of a blood-dissolving agent, or of hæmoglobin dissolved in serum, induces a condition which strikingly resembles pernicious anæmia. 9. One form of chlorosis, and also simple primary anæmia are essentially forms of hæmoglobinæmia of mild grade.—*Berliner klin. Wochenschrift*, July 26, 1886.

Vaccination in Japan.—The Japanese do not appear to have lost any of their faith in the efficacy of vaccination for the smallpox. They have just enacted a very stringent law on the subject, for, besides ordinary vaccination in the first year of infancy, it provides for at least two subsequent revaccinations at intervals of from five to seven years, so that by the time a child has reached its fifteenth year it will have been vaccinated three times. During epidemics of smallpox, local authorities also have power, when they deem it necessary, to order the vaccination of all the inhabitants of their districts, irrespective of the vaccinations required by the law.—*Sanitary Record*.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 21, 1886.

NEUROTIC ASTHMA AND OTHER NEUROTIC MALADIES IN THEIR RELATIONS TO INTRANASAL DISEASE.

DURING the past five years or so, the nose has been taking a progressively prominent position in the features of continental periodical medical literature; the main impetus thereto having been given by HACK, of Freiburg, who, under the term reflex neuroses, has spurred attention to the frequent association of diseases of the nasal passages with various nervous disorders. Stripped of both fanciful and hypothetic investiture, the naked truth seems to be that in many neurotic individuals, whether intellectually neurotic, æsthetically neurotic, neurosthenically neurotic, neurasthenically neurotic, hysterically neurotic, or in any other way neurotic, various irritations of the terminal fibrils of the fifth pair of nerves in the mucous membrane of the respiratory domain of the nasal passages, or of the nerves of special sense in the olfactory domain, are transmitted, sometimes through the tracts of the sympathetic system of nerves, sometimes through the reflex zones in the cerebrum, to various motor and sensory tracts, especially those in the domain of the pneumogastric. Thus these neurotic subjects are liable to manifestations of disease or disorder in distant organs. Taking all the publications together, the list claimed includes spasmodic asthma, bronchitis, bronchial spasm without asthma, spasm of the larynx, spasmodic aphonia, spasmodic cough, spasmodic sternutation, hysterical paralysis of the larynx, palpitation of the heart, chorea, epilepsy, cephalalgia, supraorbital, facial, and dental neuralgia, gastralgia, nightmare, vertigo, syncope, cutaneous nasal erythema, unilateral hyperidrosis of face or of extremities, super-salivation, facial œdema, and articular rheumatism: all as reflex manifestations of pathological conditions existing in the nasal passages or excited therein. It is claimed, too, that these reflex neuroses are best treated by curing the intranasal disease or diseased condition from which they are reflected; with special reliance on rhinochirurgical procedures, and particularly on such as are performed with the incandescent electric cautery.

Although pain, forcible inspirations, sternutation, lachrymation, tumefaction, and fluxion have probably always been recognized as physiological results of irritation of the normal nasal mucous membrane; and although, in suspended respiration, the abeyant respiratory and cardiac divisions of the pneumogastric, have long been habitually started into function by excitation of the nasal mucous membrane, as when ammonia is held near the nostrils of a lady in syncope; and, not to mention less recent authors who were familiar with the effects of pollen dusts, ipecacuanha powder, odoriferous emanations, and the like, so recent a writer as Trousseau had described the occasionally intimate relations of asthmatic paroxysms to nasal catarrhs and to pharyngeal disorders; and although his physiological researches had drawn from Müller the opinion that the system of respiratory nerves is capable of convulsive excitation by topical irritation of any portion of the body invested with mucous membrane (Boecker), it was not until after Voltolini, of Breslau, had, in 1871, published an account of some instances of asthma in which the paroxysms had ceased after extirpation of nasal polypi, which he, therefore, felt reason to regard as a causal factor, that the profession seemed to realize that occlusion of the nasal passages might produce morbid manifestations at a distance.

Nearly every one who has suffered with a cold in the head, has experienced sudden relief by subsidence of turgescence in one occluded nasal passage with sudden onset of obstructive turgescence in the other. If the sufferer lies with the obstructed side uppermost it will soon become permeable, while the permeable lower side will become obstructed in its turn, and then, by turning on the back so as to catch the retransition half way, considerable relief will often be secured; sufficient at times to enable the sufferer to go to sleep without keeping the mouth open. What the vascular connection between the structures in the two nasal passages that produces the interchange, awaits explanation from anatomist, physiologist, and clinician. Mere gravity will not account for transmission of turgescence from one set of turbinate bodies to the other on change of position from one side to the other; although it may explain the subsidence on both sides posteriorly when the subject lies on his back; for then the exceedingly vascular posterior portions of the turbinate bodies

may become surcharged, and so produce sufficient relief anteriorly to permit resumption of nasal respiration. When this posterior turgescence is so excessive, however, as to occlude the choanæ and prevent nasal respiration, the subject is sometimes aroused from sleep with a paroxysm of dyspnœa, often mistaken for a paroxysm of asthma; a paroxysm relieved almost at once by opening the mouth on the one hand, or on the other by raising the body to the vertical position, and thus favoring partial subsidence of the turgescence; or by a combination of the two acts, usually intuitively. Should the patient be in too narcotic a slumber to be aroused immediately by his dyspnœa, the paroxysm may become transformed into a nightmare.

The turbinated bones are invested with a mucous membrane in actual fusion with the periosteum. Upon the whole of the lower turbinated bone, on the free border of the middle turbinated bone, and at the posterior portions of all three turbinated bones, this mucoperiosteal investment is composed in great part of an embedded cavernous system of veins (Hopmann, Zuckerkandl) with endothelial walls only (Voltolini), which permits great distention of the tissue, whether physiological or pathological. Physiologically to warm the inspired air, to ward off injurious effects from sudden atmospheric changes, to keep out foreign matters, or to favor serous effusion to wash out foreign or morbid products; pathologically, the result of irritation or of disease. Similar but less extensive turgescible tissue exists in other portions of the nasal mucous membrane, in all portions, in fact, except the olfactory fissure (Zuckerkandl, cited by Hering). This turgescible mucoperiosteal investment of the lower turbinated bone, the one most frequently implicated, comprises in its quiescent attitude fully nineteen-twentieths of the entire structure of the turbinated body, the bone forming one-twentieth only (Voltolini). Some untenable hypotheses have gained credence on the assumption that the cavernous portion of the mucoperiosteum of the turbinated bodies was a special tissue or a special organ, "corpus cavernosum," distinct from the tissue proper of the mucous membrane, the periosteum, and the bone. The turgescent condition, believed by some observers to be normal, and by others to be abnormal, can be excited in some subjects by stroking the tissue with a probe; but in others this procedure fails. Persistent turgescence must be regarded as abnormal. Permanent distention of this turgescible tissue sometimes leads to thickening of the connective tissue, and perhaps to alteration in the unstriped muscular fibre surrounding the vessel, and to change in the size and number of glands embedded in the meshes of the tissue. It is then a pathological hypertrophy subject to but slight subsidence, and therefore often —not always by any means—a permanent source of irritation requiring surgical interference just as does a hypertrophied tonsil which produces continuous or progressive injurious disturbance.

Voltolini attributed the asthmatic paroxysms in his cases of nasal polyp, some with permeable, some with impermeable nasal passages, to modifications in the chemical interchanges of respiration due to mechanical obstruction thereto, rather than to reflex action; the possibility of which latter, however, he fully expressed. The infrequence of asthma associated with nasal polyp, accounts for its tardy recognition. Recently instituted statistical investigation, purposely pursued in every accessible case of asthma and of polyp, shows that not only is the proportion very small when hunted for (seven in seventy-nine cases and five of the seven in females, Lublinsky; nine in three hundred and ten cases operated upon, Boecker; six out of two hundred, Hering); but that most of the cases occur in decidedly neurotic subjects (Lublinsky), and are, therefore, reflex in origin; attributable, as expressed by Fränkel, of Berlin, some ten years after Voltolini's publication, to an abnormally irritable condition of the sensory nerves. Indeed, Fränkel had seen the asthmatic paroxysm follow the irritation of the mucous membrane as produced by the polyp. Lublinsky has called special attention to the impaired neurotic condition of all his patients with reflex neuroses of any nasal origin whatever. Many were hysterical, many anæmic, poorly nourished or psychically depressed from the most varied causes. Females predominated in his policlinic practice, and the majority of the males had become reduced in circumstances. This disproportion was not present in private practice, but here the majority of the male patients were engaged in severe intellectual labor without proper periods of relaxation.

For some time limited sensory zones have been described as evolving the reflex actions; and, in accordance with the special groups of cases which had presented, were located by different observers in certain portions of the turbinated bodies, or of the septum chiefly; the fact being, as substantiated by pretty general observation, that under various abnormal conditions of the nervous system any portion of the nasal mucous membrane may be the point of evolution for a reflex manifestation. To go further, diseased conditions of the mouth, the gums, the pharynx, the larynx, if not the entire respiratory and alimentary tracts, have been known to give rise to reflex spasmodic disorders. If to these be added the well-known reflexes from the prepuce, and those from the vagina, the rectum, and the urethra, we but come back again to the shrewd observation of Johann Müller, that topical irritation of any mucous membrane may ex-

cite convulsive manifestations in the domain of the respiratory nerve tract; and it may be added, with fair prospect of probability, in the other domains in which reflex manifestations are said to be excited by nasal disease. And so the conclusion may be reached that nasal reflexes are frequent manifestations of the irritation of mucous membranes in general; more frequent than those from other regions, because other regions are less continuously exposed to irritant influences, atmospheric, mechanical, and chemical.

Some of the manifestations attributed to reflex neuroses are doubtless due, as intimated by Voltolini in his initial article, to the change in the rhythm of respiration and the obstruction to proper interchange of the gases of the air and of the blood.

Schech, too, has expressed the opinion that the retention of too much carbonic acid gas in the blood irritates the medulla oblongata, and thus has much to do in provoking reflex neuroses. The important part that the obstruction plays is proven, according to Boecker, by the fact that a commencing paroxysm of asthma can sometimes be cut short by turning up the tip of the nose and dilating the nostrils, so as to enlarge the passage and render respiration freer. The calming effect of applications of cocaine in arresting a paroxysm is attributed by the same writer to enlargement of the calibre of the passage, and not to any anæsthetic effect upon the sensory nerve endings. The same writer has suggested, further, that direct irritations are sometimes conveyed to the tracheal and bronchial mucous membrane which, under normal conditions, are expended on a nasal mucous membrane. To reach a conclusion in any instance, all probable sources of origin must be passed in review, lest undue credit be given to the incorrect one.

That the treatment of the nasal disease evoking the reflex disorder is often essential to the cure of such a disorder hardly admits of a doubt. That such treatment is always followed by cure at a shorter or longer period admits of many doubts. Constitutional treatment addressed to the diathetic, enthetic, and neurotic imperfections of the individual is quite as essential as topical treatment within the nose, and sometimes more necessary. Such treatment, however, often inefficacious before subsidence of the intra-nasal malady, is often promptly efficacious after its subsidence. No hard and fast rule of routine can be adopted; but each case must be mana ed in accordance with the general principles of good practice and of good surgery. While the judicious use of the electric cautery in certain morbid conditions of the intra-nasal tissues is to be commended, its too frequent and growing abuse in slight ailments, more safely subdued by measures less severe, is as highly reprehensible. These views are steadily gaining the support they merit; for it is becoming more and more evident that the electric cautery sometimes does irreparable injury. Among the pernicious results reported by various writers may be enumerated adhesions of opposing surfaces, anosmia, severe hemorrhage, erythema, traumatic erysipelas, œdema of the palate, necrosis of the bones, otitis media, meningitis, temporary delirium, rheumatic swellings (sepsis?), febrile herpes, neuralgia of the fifth nerve (?), epilepsy, and asthma.

It is questionable whether the erectile tissues should be utterly destroyed under any ordinary circumstances, for an atrophic condition of the turbinated bodies is to be deplored as liable to convert an affliction that is bearable into one that is very disagreeable and mortifying.

THE CUTANEOUS ABSORPTION OF OILS.

Recent clinical experience with lanolin has shown that this oil is readily susceptible of cutaneous absorption, and that on this account it is more valuable for external use and for purposes of massage than are the less diffusive organic oils or than petrolatum, which is practically unabsorbed. Ewer in the *Berliner medicinische Wochenschrift*, for July 8, 1886, points out a further advantage possessed by lanolin over similar bodies, namely, that after thorough inunction in massage the remaining lanolin may be thoroughly removed by wiping with a dry cloth. When other fatty bodies have been thus employed subsequent washing with water, and even warm water and soap, becomes necessary, a procedure often disadvantageous, especially in rheumatic joint affections.

No thoroughly scientific study of the extent to which the neutral fats may be absorbed by the healthy skin has been made, but abundant clinical evidence exists that such absorption takes place, and that it, together with the benefits derived from the act of inunction, exerts a stimulating influence upon the general processes of nutrition.

One of the earliest modern studies in this subject, but one now rarely cited, is that by Sir James Y. Simpson in the *Edinburgh Monthly Journal of Medical Sciences*, for October, 1853. He collected and recorded considerable information from physicians practising in the neighborhood of woollen factories which tended to show that those employed in the more oily processes of woollen manufacture possess a noteworthy immunity from tubercular and scrofulous disorders, and also that they were largely exempt from epidemics of scarlatina, measles, and cholera. He relates a case in which a patient by the external application of oil and with no other change in his food or treatment gained twenty-four pounds in forty-two days, and another case of a child who gained an ounce daily throughout eight weeks of similar treatment. Simpson maintained that the ab-

sorbing power of the skin increased by practice, and that the major part of a wineglassful of warm oil could, with care, be daily rubbed into and absorbed by the skin.

In 1858, Dr. J. B. Thompson, who was, during seventeen years, surgeon to various woollen factories, emphatically corroborated, in the same journal, Simpson's thesis. He reports that in Glasgow and Aberdeen the contrast between cotton and wool workers is attested in favor of the latter, by the factory inspectors and consulting surgeons; and that in Yorkshire the better classes frequently send the delicate members of their families to the woollen mills for the benefit of their health. Of 100 young persons of from 13 to 18 years of age thus employed and under Dr. Thompson's observation, there occurred, in the course of three months, an average individual gain of 5¾ pounds. Of these a *selected* eight exhibited an average increase of 17 pounds each within the time named. None of those under observation lost weight, and one, a phthisical patient, gained 2 pounds.

Sufficient has been said to show that in inunction we possess a means of stimulating nutrition which might with advantage be more frequently used than it is at present.

HÆMOSTATIC ACTION OF FARADIZATION OF THE UTERUS.

Ramas, of Brazil, narrates, in the *Bulletin Général de Thérapeutique*, 1886, No. 1, the case of a patient who, for three months after an abortion, exhibited a scanty but constant uterine hemorrhage. Careful examination revealed no undetached portions of placenta, nor uterine tumor or polyp. The usual methods of treatment by ergotin, liquor ferri, tamponing, and hot injections were without avail.

As a last resort electricity was used, one pole being placed on the abdomen above the symphysis and the other applied directly to the neck of the uterus. The treatment was painful, but the bleeding ceased in five minutes, to return in three days, when a second application caused its permanent cessation.

Apostoli had previously advised a similar use of electricity in metritis and displacements.

REVIEWS.

The Principles and Practice of Surgery. By Frank Hastings Hamilton, A.M., M.D., LL.D. Third edition. 8vo. pp. xxxii. 989. New York: William Wood & Co., 1886.

Dr. Hamilton is too well known to make it necessary for us to copy the list of titles by which he has been honored, or to cite the positions which he has occupied, and which have been honored by him. He is looked up to by the entire profession as one who is entitled to confidence, and whose experience and ability give the weight of authority to his expressed opinions. This new edition of his *System of Surgery* will, therefore, be gladly welcomed by all, and his views on many points eagerly canvassed by those who desire well-considered judgments, coming, as they do, from one whose professional career covers nearly the whole area of modern improvements in surgery.

As a system, however, the work is disappointing, which is inevitable from its narrow limits, but as a record of personal observation it is very valuable. We regard surgical observations given to the world in the later years of one who has had extended opportunities among the most valuable of literary productions. Had Dr. Hamilton restricted himself to writing such a book it would have contained the cream of this one, and enabled him to give at greater length personal experiences, unhampered by the necessity of constant condensation on account of the extended field over which he must necessarily go in completing a systematic work.

But it is time we ceased profitless speculating over what might have been, and said a few words concerning the book as it. It has two grand divisions dealing with general and regional surgery, the first part containing twenty-four, and the second part twenty chapters. In these chapters pretty much the whole realm of surgery is gone over with more or less thoroughness, but with much brevity. Even diseases of the eye, ear, and nose have chapters devoted to them. But, as we have already said, it is on account of its containing the matured opinions of Dr. Hamilton that the work will be studied. Those opinions are given concisely, but with all their author's vigor of expression, and generally the reader is left in no doubt as to the course which Dr. Hamilton himself would pursue in a given case. We regard this feature as a most important one, for while dogmatism in the young and inexperienced surgeon is out of place, and may lead to the adoption of novel and often unwise experiments on the part of his readers, it is fitting that one who has had experience should speak with decision. We have been much interested in the estimates placed upon different forms of amputation, and believe that they may generally be regarded as worthy of full confidence, and that they may be safely followed. The concluding chapters, in which modern methods of dressing wounds are glanced at, are also full of interest, and may be read with much profit.

SOCIETY PROCEEDINGS.

THE AMERICAN OPHTHALMOLOGICAL SOCIETY.

Twenty-second Annual Meeting, held at the Pequot House, New London, Conn., July 21 and 22, 1886.

(Concluded from page 193.)

Dr. B. Alexander Randall, of Philadelphia, reported

TWO CASES OF SEVERE TRAUMATISM OF THE EYE, WITH PARTIAL DISLOCATION OF THE CRYSTALLINE LENS.

In the first case, a man of fifty years, there were three points of rupture of the sclera visible on the upper

surface of the globe, with some tendency to hernia of the contents. The upper half of the lens was in the anterior chamber in front of the iris, the lower half apparently being in nearly the normal position. Its extraction was advised, but delay being asked, the operation was deferred. The lens receded under rest in bed and other appropriate measures. The scleral rupture healed, and in spite of disseminated opacities in the lens and in the vitreous, which prevented at any time a view of the eye-ground, the vision increased to about one-thirtieth of the normal. The patient has since been at work and fairly comfortable, the other eye giving no suggestion of sympathetic trouble. The injured eye shows little tendency to grow worse, although the lens is still luxated backward.

In the second case, patient a boy of twelve years, the lens was less markedly luxated, but the ophthalmoscope showed two rents in the choroid, the larger, a little outside of the macular region, the other close to the temporal margin of the optic disk. In connection with the latter, there was a reddish area of choroid, embracing the upper and inner border of the disk, where the force had apparently been insufficient to rupture the membrane, but had given it a twist, causing its inflammation and subsequent atrophy. The case progressed to an excellent recovery. The vision, which had been lost, improved to $\frac{6}{12 + \text{m}}$, and the accommodation to the extent of some five dioptrics. The choroid rents healed with little but pigmentation to mark their sites. The eye, which had shown a high degree of myopic astigmatism, probably by reason of the dislocation and rotation of the lens, returned to the approximately emmetropic condition of the other eye.

The early and late appearances of the eye-ground were illustrated by colored sketches.

Dr. J. S. Prout, of Brooklyn, read a paper on

BADAL'S OPERATION: LACERATION OF THE INFRATROCHLEAR NERVE FOR THE RELIEF OF GLAUCOMA, ETC., WITH CASES.

In 1882–83, Badal, of Bordeaux, proposed the laceration of the infratrochlear nerve (*nerf nasal externe*, of the French) for the relief of glaucoma accompanied by pain. This nerve is the direct extension of that branch of the ophthalmic, the nasal, from which the eyeball receives its nervous supply. It emerges from the orbit just below the insertion of the pulley of the superior oblique muscle, and supplies the skin at the root and side of the nose and the caruncle, lachrymal sac, and nasal duct. It is readily reached by an incision along the margin of the orbit running from the pulley to the upper margin of the tendon of the orbicularis muscle. It is small, soft, not easily recognized, lies on the periosteum and is to be taken up by a hook with its accompanying vessels and stretched and torn by pulling directly forward. Very little bleeding occurs. Sutures are used to close the wound, which, under ordinary dressing, soon heals. Small painful nodules are sometimes left at the point of rupture. No anæsthetic is needed, as the time required is brief, and there is but little pain except when the nerve is torn. The rationale of the operation is not explained.

In severe cases, when a short delay may be fatal to the eye, he advises that the operation be combined with evacuation of the aqueous tumor. A great advantage of the operation is that, as it does not attack the eyeball, it will be accepted by patients much more willingly than a sclerotomy or an iridectomy. Four of his patients assented to it only on condition that the eyeball should not be touched. When it has failed, he has not had better results from other operations.

Badal, in 1883, reported his results in twenty operations on eighteen patients, nearly all of whom were unpromising for any operation. Pain was relieved at once in ten cases, rapidly in one, gradually in five, not stated in four. Tension was relieved quickly in four, gradually in eight, not relieved in six, not stated in two. Sight had been long lost in seven. It was improved in four, not improved in four, and not stated in five.

Dr. Prout had performed the operation nine times on five patients. All were unpromising cases. In one there was for a time decided improvement of vision; in one there was temporary relief from moderate, and in one from severe pain. One was a case of glaucoma simplex operated on without benefit; another a case of hemorrhagic glaucoma, not benefited. Others have reported much better results. In the *American Journal of Medical Sciences*, for July, 1886, Dr. C. S. Bull refers to a paper by Lagrange, who strongly commends the operation as efficient, especially against the agonizing pain.

Dr. Prout drew the following conclusions: The operation has been shown to deserve further trial, especially in cases unfit for operations on the eyeball; it cannot make matters worse as to the eyes; relief of pain, even if only temporary, is worth procuring at the cost of a slight operation; it is important that cases be recorded so that the value of the method may be ascertained.

Dr. C. S. Bull, of New York, said that in the cases where he had performed the operation for the relief of pain in glaucoma or ciliary neuralgia, while the relief was marked immediately after the operation, it was temporary only, and in every case the pain returned.

Dr. H. Knapp, of New York, read a paper on

ADVANCEMENT OF TENON'S CAPSULE IN STRABISMUS.

This operation was devised by de Wecker five years ago in the following manner. A piece of conjunctiva, five millimetres long and ten millimetres high, is detached from the region of the insertion of the tendon as a centre, leaving a small band near the cornea. Tenon's capsule is now incised near the insertion of the tendon and loosened alongside of and under the muscle. The capsule is then stitched forward by two sutures, entering through the conjunctiva to the capsule at the lower and upper edges of the muscle and coming out in the conjunctiva above and below the cornea. The greater the piece of capsule loosened and stitched forward the greater the effect. If the effect appear too great, the stitches are removed the next day. If not, they are allowed to remain four or five days. De Wecker used capsular advancement for cases of insufficiency to strengthen the weak muscle; for high degrees of strabismus, both convergent and divergent.

Dr. Knapp, during the present summer, had done the operation ten times. His operation differed from that above described in leaving a broader conjunctival flap and in using a third middle suture. His intention was to advance the whole anterior portion of the vertically

folded muscles and the capsule and produce plastic inflammation, which, through subsequent cicatrization, should shorten the parts. The operation was performed in two cases of convergent strabismus due to paralysis of the external rectus. In these cases the operation caused decided improvement. The eyes could be approached to within four millimetres of the outer commissure. The formerly paralyzed external muscle had gained a considerable degree of power. The operation was performed on two cases in which former tenotomies had not overcome the difficulty. The operation was followed by improvement in both cases. In six cases the operation was performed for convergent strabismus of high degree with considerable amblyopia. The results have all been quite good.

In none of the cases has there been any alarming reaction, although there were for some weeks redness and swelling in the region of the advanced capsule. At first, Dr. Knapp had used catgut sutures, but one gave way on one occasion and since then he has employed black silk sutures. Antiseptic precautions were employed in all cases. The speaker preferred advancement of Tenon's capsule to simple advancement of the tendon, because the operation is simpler and attended with less risk. The preservation of the natural attachment exposes the muscle less to inflammation, and there can be no undue retraction in cases of failure. His experience with limited advancement of Tenon's capsule has been quite encouraging.

Dr. George C. Harlan, of Philadelphia, asked whether this is a safe operation? Four or five years ago he did it a number of times and was much pleased with it until he had a case of panophthalmitis. Antiseptic precautions were not employed at that time.

Dr. H. Knapp replied that a year ago he considered it a dangerous operation, but that his views had changed considerably since then. Under antiseptic precautions the danger is much lessened. Where suppuration occurs within the first twenty-four hours, it is certainly the result of infection and not due to the traumatism alone.

Dr. Emil Gruening, of New York, reported

A CASE OF TUMOR OF THE LEFT OCCIPITAL LOBE.

The chief interest of the case lay in the fact that the disease of the brain was localized by the existence of homonymous hemianopsia. Diagrams showing the course of the optic fibres were exhibited. At the autopsy a hard mass was found in the left occipital lobe and the whole cortex of the lobe was destroyed.

Dr. J. S. Prout, of Brooklyn, reported a case of

NEW FORMATION IN THE VITREOUS OF BOTH EYES.

The patient was a man, aged twenty years. He had never had any trouble with the eyes. In the right eye there is a body arching forward. There is no evidence of any relation to the pupilla. The speaker thought that in all probability it was a remnant of the fœtal circulation of the vitreous. In the left eye there was a similar body. Drawings showing the appearance presented were exhibited.

Dr. Edward Jackson, of Philadelphia, presented a *Lens Series for the Refraction Ophthalmoscope*.

Dr. John Green exhibited and described a *New Series of Test Letters*.

Dr. Charles A. Oliver, of Philadelphia, presented a *Set of Metric Test Letters and Words* for determining the amount and range of accommodation. They are made of six sizes of differently arranged words. Each word contains three or four of the seven letters, C D E T O L F Each letter is made in exact conformation with the Snellen basis. The adoption of such a series puts the determination of the acuteness of vision and of accommodation upon a uniform basis.

Dr. S. D. Risley, of Philadelphia, reported

A CASE OF RETINITIS ALBUMINURICA; INDUCED PREMATURE LABOR.

The patient, the wife of a physician, was seen September 24, 1884. She was between the fourth and fifth month of her third pregnancy. She had suffered with headache and giddiness. The urine had been examined a week previously and no albumen found. At this time there was marked disturbance of vision. In a previous pregnancy she had had albuminuria, but no trouble with sight. In the second pregnancy there had been no trouble.

The ophthalmoscope showed albuminuric retinitis of both eyes. The urine contained a large quantity of albumen. After consultation with her husband and Dr. William Goodell, the induction of abortion was advised, but to this the patient positively refused to consent. Finally, after consultation with her clergyman, she consented.

Labor was induced and she was delivered of a fœtus at five months. She then passed into an unconscious condition, in which she remained four days. There were no convulsions; as consciousness gradually returned, evidences of right hemiplegia with aphasia were noted. The quantity of albumen gradually diminished. Six months later the lady was able to return to the office. There were still some traces of aphasia. Vision was greatly improved.

The object in reporting the case was to put on record an additional experience in this problem presenting so many serious considerations.

Dr. B. Alexander Randall exhibited a *Modification of the Loring Ophthalmoscope*, which consisted in adding a series of cylinders from 0.25 D. to 4 D.

Dr. J. A. Andrews, of New York, read a paper on

THE FREQUENT INSTILLATION OF A TWO PER CENT. SOLUTION OF NITRATE OF SILVER IN PURULENT OPHTHALMIA.

He had employed this method in twenty-five cases of gonorrhœal ophthalmia and the eyes were seriously damaged in none of them. The cases were all severe, with much discharge, chemosis, and swelling of the lids. The applications were repeated usually three times a day, sometimes as often as five times per day. The use of the nitrate of silver is graduated to the amount of hyperæmia, and especially to the amount of swelling of the lids. If this is marked, he does not fear to repeat the instillations frequently.

Dr. Russell Murdoch, of Baltimore, exhibited an *Impervious Covering for the Sponge in the Administration of Ether*.

Dr. H. D. Noyes, of New York, presented a paper on the *Measurement of Astigmatism by the Ophthalmometer of Javal and Schiotz*. The instrument is useful for purposes of rapid determination, for confirmation, and in doubtful cases for diagnosis.

Dr. H. D. Noyes also read the following papers by title: *Burns of the Eye by Fulminate of Silver and Fulminate of Mercury*, and *Cases of Foreign Body in the Globe, including Two Cases of Spontaneous Extrusion.*

OFFICERS FOR THE ENSUING YEAR

were elected as follows:

President.—Dr. William F. Norris, of Philadelphia.

Vice-President.—Dr. Hasket Derby, of Boston.

Secretary and Treasurer.—Dr. O. F. Wadsworth, of Boston.

Corresponding Secretary.—Dr. J. S. Prout, of Brooklyn.

The next meeting will be held at the Pequot House, New London, Conn., on the third Wednesday of July, 1887.

Adjourned.

CINCINNATI ACADEMY OF MEDICINE.

Stated Meeting, May 24, 1886.

(Concluded from page 138.)

The President, James T. Whittaker, M.D., in the Chair.

THE SURGERY OF ECHINOCOCCUS.

Dr. Joseph Ransohoff remarked that in the consideration of this part of the subject, the question of diagnosis plays an important *rôle*. A liver riddled with cysts, like the specimen presented, is not, as the surgeon who operated properly remarked, one adapted for surgical interference of the nature resorted to. It is an evidence, possibly, of the limit of our insight into the condition of disease, that a diagnosis which was as brilliantly made as the one in the case reported should not have been absolutely perfect. Had a compound echinococcus been recognized, it is quite certain that the ventrocystorrhaphy would not have been practised. The speaker regretted that the gentlemen who had devoted their time to the diagnosis of this disease had said nothing upon the point of differentiation between the simple and compound cyst. In looking at the specimen and in hearing the history of the case as reported, and particularly the reference to the presence of at least two or more protuberances from the hepatic surface, a suspicion as to the possible existence of a compound cyst might have been aroused. The fact that this suspicion did not arise, even after the larger cyst was aspirated, affords conclusive proof to the speaker that the differential diagnosis between simple and compound cysts is, in the present status of our methods of investigation, not always practicable. Irregularity in the outline of the hepatic margin, a feeling of nodulation, as it were, is probably the most valuable sign of the existence of numerous and distinct cysts.

So far as the treatment of hepatic hydatids is concerned, it is quite certain that in many cases nothing more than aspiration will be called for. It has been established that emptying the contents of the "bladder-worm" usually puts an end to its life history. Nor is the operation of aspirating a hydatid of the liver a dangerous procedure. Death has followed puncture, either from the escape of fluid into the peritoneal cavity or from the puncture of a large hepatic vein as happened in Mr. Bright's case. Such disastrous results are very rare after puncture. In thirty-five out of forty-six cases collected by Murchison, in which it was resorted to, it was successful. Only one case terminated fatally from peritonitis. In ten of the forty-six cases the puncture was followed by suppuration, thus necessitating, as in the case reported, secondary incision of the sac. Of these, eight recovered and two died. When turbidity of the sac contents, or pain, indicates the presence of inflammation, the time for the usefulness of simple puncture has passed. The same is true in cases of endogenous growth of the hydatid tumor, where the removal of the contents of the mother-cyst is not always directly fatal to the younger cysts within. In all of these cases a free opening of the sac is a *sine qua non* of a successful issue. There are many ways of doing this: either by the use of a single trocar of large size, or by the use of two trocars and subsequent incision, or by the preliminary use of a caustic to secure adhesion or by ventrocystorrhaphy may the echinococcus be incised. With a fair knowledge of draining an abdominal wound and with a fair skill in suturing the cyst-wall to the abdominal wound, most cases treated after the last-named method will get well. It is a method successfully resorted to in hepatic and pelvic abscesses, in pancreatic and exceptional cases of ovarian cyst, and has been largely practised in hydatids of the liver in Germany. Even had a more accurate diagnosis been possible in the case reported, any method would in all probability have failed. The one which would have promised most is that by electrolysis. It is known that in simple cysts and in young subjects the use of electricity has been beneficial. In cases of compound hydatid it appears particularly applicable in view of the fact that without it or multiple aspiration a successful surgical interference can hardly be hoped for.

Dr. P. S. Conner remarked that he could not decide where the last speaker could have gotten his information regarding the appearance of the tumor. The tumor had no such nodular feel as has just been described. There was, as stated before, one large round mass and a smaller round mass beside it; there was nothing to indicate at the time of the operation that the cysts were so numerous or that the liver was so filled with them, and it would have been a matter of impossibility to have determined at that time the existence of more than two cysts. There was one large rounded mass which had been emptied more than once and had refilled, and a smaller one near it. As stated in his former remarks, this was not a case for operation; but this conclusion could be arrived at only after the post-mortem examination.

Two facts are very clear in the history of hydatid disease of the liver. One is that there is an almost absolute certainty of its ending in death—in the course of four or five years at the outside, as a rule; and the other is that medical treatment is of no value. The disease, if it is to be influenced at all in its course, must be so influenced by active interference with instruments. There is really no new operation for the disease, for all our present operations are but the old operations or modifications of them. It is forty years since an Iceland physician recommended the use of electricity, and tapping is yet older. All operations at present have for their object the destruction of the hydatid, so that the fluid may be absorbed and perhaps calcification of the cyst take place, or else that suppuration may occur and per-

mit the conversion of the cyst into an abscess, to be treated like any other abscess of the organ; or, lastly, the removal of the cyst in mass. Aspiration is by no means an operation devoid of danger, and it certainly is not one to be recommended more than twice or, at most, three times in the treatment of a given case. Indeed, we may safely declare that as soon as suppuration occurs, the use of the aspirator needle is positively contraindicated. It has been shown more than once that even when an excessively small quantity of this hydatid fluid has found its way into the peritoneal cavity it has excited violent inflammation and caused death, but not invariably or necessarily so. It has further been found that after tappings, sometimes after the first, frequently after the second, very frequently after the third, and always after repeated tappings, suppuration occurs. It has, therefore, been positively stated that aspiration should be practised only once, and that repeated puncture should never be made. So far as danger to life is concerned, it has been shown that repeated punctures are more dangerous than a single puncture kept open, especially when such is made with a large trocar, and drainage is maintained through a large tube. At the present time, aside from aspiration, recourse is had almost invariably to opening the cyst, and that either at a single sitting or at two sittings, adhesion of the peritoneal surfaces being secured before the cyst is cut into. The old Récamier treatment by caustic applications that was so likely to cause peritonitis, and so often failed to secure adhesions, may certainly be regarded as a thing of the past. Incision of the cyst is an operation fifty years old or more, and it was repeatedly tried and abandoned on account of the excessive mortality which attended it in what is now known as the preantiseptic period. Lehotsky has recently reported twenty-five cases, four coming under his own observation, death occurring only four times, in three of which instances the fatal termination could not fairly be attributed to the operation. But even if, as has been declared by Niessen, the mortality of the operation reaches one-third, still the mortality is so much less than that which attends the do-nothing treatment, that it demands consideration.

If the cyst lies immediately under the surface of the liver, it is an easy thing to determine what is to be done; but if it lies at some depth, the decision is more difficult. Still, there is only one thing to be done, and that is to go deeper until the cyst is reached. If there has been effusion of the cyst contents into the pleural cavity, the ordinary free operation for empyema must be made.

In conclusion, Dr. Conner said, there is so great a mortality attending the let-alone treatment (and the risk of aspiration is by no means a slight one) that there can be no question as to the propriety of making an incision into the cyst. Cases presenting peculiarities may demand special treatment—*e. g.*, removal in mass or ligation of the pedicle and cutting away the major part of the sac. The peculiarities may even be such as to add seriously to the difficulties of diagnosis. In one of Pean's cases in which the tumor projected directly forward in mass as large as a child's head, it rested on the abdominal aorta so as to receive an impulse from that vessel, showing that it may be possible for a liver hydatid to be mistaken for an abdominal aneurism.

ECHINOCOCCUS OF THE EYE.

Dr. David de Beck remarked that the interest the disease might have in ophthalmology was purely clinical. About forty cases of echinococcus of the eye have been reported; all these by French and German writers, none by Americans. The echinococcus in this region is distinguished from the cysticercus in that the former cyst is always found in the orbit, whereas the latter usually occurs under some of the membranes of the eye and is termed subconjunctival, etc. Only three unquestioned cases of cysticercus of the interior of the eye have been reported. In most cases of this affection the diagnosis has been made after the operation for its removal.

Dr. Whittaker, in concluding the discussion, said that as the hour for adjournment had arrived he would make but two or three remarks. He had already spoken of the rarity of the disease in this country, with the reservation that undiagnosticated cases recognized on autopsy are not reported. One of our hospital pathologists here said that he had seen three such cases in this city. Failure to recognize echinococcus is not confined to this city. Thierfelder observes that but seven of thirteen cases were discovered during life at Rostock, and Bröcke states that but thirteen of twenty-two cases were recognized at the Berlin Charité. Madelung maintains that only about one-third of the cases are generally diagnosticated during life. It must be remembered, however, that most of these cases occurred before the days of aspiration. The use of the aspirator simplifies the diagnosis immeasurably.

He thought that for practical purposes the chemical is superior to the microscopic test, as it is the exception, and not the rule, to find either scolices, hooklets, or characteristic fragments of membrane in the specimens examined.

It was his opinion that most cases outside of Iceland were not contracted directly from dogs, as there is nowhere else such intimate relation with dogs. Besides, dogs are not so frequently affected with tænia as is commonly believed. Krabbe, of Copenhagen, examined the bodies of 500 dogs with reference to this point and found but 0.6 per cent. affected with tænia echinococcus. König intimates that the use of the *album grecum*, the dried feces of dogs, as a medicine, by the common people of Mecklenberg, might account for the frequency of the disease in that country. Paullini, in 1699, wrote a book on the virtue of excrement in the cure of all disease. But most of the druggists respond to the call for the "*witten entzian*," as it is called, with magnesia, and Madelung observes that when the real *album grecum* is furnished, it is old desiccated matter long exposed to the elements, whereby all organic matter is thoroughly destroyed.

The view that most cases come from sheep, by the ingestion, not of the ova, but of the cysts themselves in the liver of this animal, is supported by the frequency of the disease in Victoria, where the proportion of sheep to human beings is 100 to 1. Victoria ranks next to Iceland in the frequency of deaths from this disease.

Wechselmann, of Rostock, has made an intensely interesting contribution to the subject of the effects of bile upon echinococcus cysts, based upon the reports of twenty-five cases in which this accident occurred. Grünberg and Löbaker had expressed the opinion that

the prognosis was thereby rendered more grave, but wider experience has shown that bile has rather a favorable effect through its antiseptic properties. Uterhart observed that the clear fluid of echinococcus usually becomes opaque in twenty-four and decomposed in thirty-six hours, while, when mixed with bile it remains pure and without odor for six days, and begins to give the odor of decomposition only on the seventh day. Kussmaul, likewise, remarks upon the antiseptic effect of bile upon pus, and Bartels used diluted ox-gall successfully as an antiseptic in a case of peripleuritic abscess. But in none of Wechselmann's cases could it be said that the bile exercised anything like a curative influence. The compound character of the present case could not have been recognized by any possibility *intra vitam*. The liver, as stated, was enlarged uniformly, and was by no means as large as many an amyloid liver. The speaker had seen many cases of abscess in which the liver was not larger than in this case. In fact, the whole circumference of this liver, as stated upon the exhibition of the specimen to the Academy a few weeks ago, was but twenty-three inches. The greatest diameters were eleven to fourteen inches. When pathologists teach us how to distinguish in life between endogenous and exogenous echinococcus cysts, we shall be better able to recognize compound cysts. He insisted that these cysts should be called compound, not multilocular. A multilocular echinococcus, as has been sufficiently emphasized this evening, is a very different condition. It occurs so extremely rarely—but one case in one hundred and eighty—as to have insignificant practical value.

CORRESPONDENCE.

FARADIZATION IN EXTRAUTERINE PREGNANCY.

To the Editor of The Medical News,

Sir: But for several palpable inaccuracies in the statements of Mr. Lawson Tait given in The Medical News of August 14, 1886, and the expressed wishes of medical friends, I should have allowed his letter to you to have remained unanswered, as a journalistic contest is not at all to my taste. With what Mr. Tait says of me personally, I have nothing to do, but his remarks involve the diagnostic ability of many who stand high in the ranks of American gynecologists. He appears to think that an extrauterine pregnancy cannot be detected in the early stages of its formation, and that all those who claim to have done so, and to have destroyed the fœtus by faradization, have been in error. He still insists that needles are used in the fœticidal act, although assured that in no instance has electrolysis or galvanopuncture been employed in this country. Mr. Tait should bear in mind that faradization has been resorted to in America in cases where the fœtal development was computed at from eight weeks to more than four months; whereas, in his twenty-five reported cases of ligation and incision, rupture took place so early that he was able to find the fœtus in only two of them. He calls these "*primary*" laparotomies, and finds fault with me for stating that there had been but 19 of this class, with 15 deaths, when he had himself saved 24 out of 25. I was slightly in error here, for two cases reported as having been saved under Dr. August Martin, of Berlin, have, by a paper directly received within a few days, been shown not to belong to the primary list, one fœtus having been carried twelve years, and the other three months. This brings me back to the original record searched out by Prof. Litzmann, of Kiel, in which are 17 cases and 2 recoveries.

What is a *primary* laparotomy in cases of extrauterine pregnancy? Certainly not such as Mr. Tait would make it appear. The classification into *primary* and *secondary* is much older than this operation of his, and has a very decided bearing upon the prognosis of an extrauterine case, the first having for years been the opprobrium of obstetrical surgery, while the second has been many times performed with success. The *primary* operation is undertaken in the interest of two lives, and the fœtus must not only be living, but viable. The *secondary* is performed a sufficient time after the death of the fœtus to effect the changes in the vascular supply of the placenta which follow upon the cessation of its functional activity, and thus secure its exfoliation without hemorrhage. Mr. Tait says that he has performed 7 of the primary laparotomies recognized as such in the obstetrical works of Playfair and others, and has saved 6 of the women, and that 3 of the children are now living and growing up. I can find but one of these reported as yet, and hope he will make a full statement of his method of operating upon the six that recovered, so that others may profit thereby and enter upon a field of surgery in which he alone shines as a victor, having saved thrice as many out of seven women as the rest of the world has out of seventeen.

Possibly Mr. Tait may make an exception as to the diagnostic acumen of Prof. T. G. Thomas, one of the operators referred to in his letter, when he learns that the little fœtus destroyed by him has more recently escaped by the patient's rectum. For one, I should be as much inclined to trust the diagnostic ability of Dr. Reeve, of Dayton, Dr. Garrigues, of New York, and others referred to by him, in cases such as they claim to have operated upon, as I would that of Mr. Tait himself, who is by no means infallible, although very expert. If the rectal method of Simon was requisite in a difficult case, I should have much more faith in the skilful little hand of a Morisani than in his. If Dr. M——, of Buffalo, made a mistake in one of his cases, what right has *he* to claim that he must have done so in his other five. If a surgeon, ordinarily skilful, plunges a trocar into a cancerous tumor of the liver, in the belief that he is about to open a hydatid cyst, must it be claimed that he is never to be able to make a true differential diagnosis? It is a mistake to claim that a woman has no symptoms that would direct an obstetrician to the discovery of an extrauterine pregnancy. She may not have had in the twenty-three cases in which Mr. Tait did not find any fœtus, but at a later period she has feelings that, if expressed, would, in many instances, lead a man of skill to recognize her abnormal state. This, I am assured of, would have been the case in a lady who recently died from rupture of a fœtal cyst in this city, had she spoken of her sensations in time. The obstetrical surgeons of this country, especially those who have had a large obstetrical experience, are by no means defective in skill when it becomes necessary to decide upon the nature of an abnormal growth

within the pelvis. Mr. Tait will admit the fact that a Fallopian fœtal cyst, when it has not ruptured early, will often gravitate into the Douglas cul-de-sac as it becomes heavier, provided it be located near enough to the distal end of the tube to admit of it. In such an event the test of *ballottement* may be and has been used, and the fœtus has been removed through the vagina by incision. It is in this location that the fœtus has been destroyed by faradization *without needles*.

Robert P. Harris.

329 South Twelfth St., Philadelphia,
August 16, 1886.

To the Editor of The Medical News,

Sir: In your issue of Aug. 14, 1886, I notice a letter from Mr. Lawson Tait in which he alludes to a specialist in Buffalo, evidently meaning the writer, in the course of which he throws doubt on my diagnosis of "six successful cases of electrolytic treatment of ectopic gestation," which he says I have repeatedly stated that I have had.

Mr. Tait does not make his assertion as coming second-hand, but as a generally accepted fact, patent to all. As I never saw Mr. Tait, though I hope to have that pleasure some day, he must refer to my written statements.

The only article on this subject I have ever published was in The Medical News for July 11, 1885, in which I reported "four (not six) cases of extrauterine pregnancy."

One of these cases was in the practice of Prof. E. V. Stoddard, of Rochester, and was never seen by me, as I distinctly state. Of the three which came under my own notice, the first was suffering from rupture of the sac into the broad ligament when I first saw her. I concluded that the child was dead and that the woman would probably recover, but "in order to make sure of the death of the child I advised that a current of electricity should be passed through the swelling every day for a week. This treatment was carried out and the prognosis fully justified." The second case went to term with a living child, which was removed by laparotomy after its death. One other case remains, and that I shall always believe was an undoubted case of tubal pregnancy, cured not by electrolysis but by electric fœticide.

In my published record, then, I have never claimed to have seen but one successful case of the electrical treatment of ectopic gestation.

Of the fifth case, Mr. Tait could have been cognizant only by hearsay, as I never have published a word of it. The woman had a tumor at the side of the uterus, with certain indefinite symptoms, which I thought might indicate an extrauterine gestation. I used electricity after she had refused laparotomy, and she got better but passed out of my sight. I was never sure of this diagnosis and never reported the case or considered it of any value as evidence—as I did not know its termination.

The sixth case to which he refers, and which he says I was made to discover was nothing of the kind, was as follows:

The woman came into the hospital to be delivered, firmly believing that she was pregnant. As labor did not come on, I was asked to see her and diagnosticated a tumor attached to the uterus and no uterine gestation. Dr. R. S. Sutton, who happened to be visiting me, agreed in this opinion, but was not prepared, in a hurried examination, to diagnosticate the character of the tumor, being inclined to the belief that it was a fibroid. After keeping her in my ward for a while and carefully examining her under ether, exploring the uterus with my finger and questioning her repeatedly, I came to the conclusion that the tumor was connected with the tube, and that it *might* be a case of tubal pregnancy. I, therefore, applied the battery several times, after which she got up, professing to feel much better, and at her urgent request I sent her to her home in the country without ever having been entirely satisfied with my diagnosis. Now what was the result? Soon her pain returned, and my friend, Dr. W. G. Wylie, of New York, was called to see her. He wrote me, and I gave him my view of the case, stating *positively* that it was one of extrauterine pregnancy. This I did, as I had received only the day before a letter from the patient in which she stated that her physicians (two) had both detected undoubted fœtal movements in the tumor, which would, of course, make the diagnosis conclusive. This, as it turned out, was not true, but I thought it was when I wrote Dr. Wylie. Dr. Wylie did abdominal section and found a "cyst of the Fallopian tube" with very thick walls "containing three pints of clear, straw-colored fluid" (*American Journal of Obstetrics*, January, 1886, p. 75).

What was the cause of the cyst? May it not have been a tube dilated by an ectopic gestation, and may I not have been right after all? I maintain that this is within the bounds of possibility, as it is well known that a fœtus, when destroyed early in pregnancy, may be entirely absorbed. In support of this, I have in my possession an ovum which I removed intact from the uterus, in which no trace of the fœtus could be found, though the placental remains were there and a trace of the cord.

I have seen several other cases of supposed ectopic gestation, but in none of them have I ever claimed, verbally or otherwise, to have killed the fœtus by electricity. So the six cases are narrowed down to one. If Mr. Tait would give a little more time to that "patient investigation of statistics" which he so much admires in Dr. Harris, he would not so frequently lay himself open to adverse criticism.

One word more. Mr. Tait states that "it is perfectly impossible to recognize them [cases of extrauterine pregnancy] before rupture has taken place." Perhaps, if he would study the symptomatology of the accident, follow the American method, and examine his patients in the normal position, and spend a little more time in his examinations than he confessedly gives, he might do better in the matter of diagnosis. Certainly, the Americans, to say nothing of other nationalities who have claimed to have succeeded in making the diagnosis, are some of them so eminent and so skilful that their combined positive testimony must much more than outweigh the unsupported negative opinion of any one man, no matter how distinguished he may be. I will only mention, among others, the names of Emmet, Thomas, Lusk, Mundé, B. Emmet, and Garrigues, in New York City alone. Almost the entire medical world is against Mr. Tait when he says

that "they give rise to no symptoms at all until rupture has taken place." Scores of cases might be cited to prove the contrary, but I will not take up any more space, as Dr. Harris will, doubtless, have something to say on this point.

Matthew D. Mann.

Buffalo, August 15, 1886

To the Editor of The Medical News,

Sir: The gist of the question as to the value of faradization in extrauterine pregnancy depends largely upon one point in diagnosis. Mr. Tait says, in his letter in The News of this date, that *no* symptoms of trouble arise until *after* rupture has taken place in tubal pregnancy, and that women do not complain until this deplorable event has occurred. Further on, he talks of "electrolysis" by faradization, and mixes "galvanic needles" just as unnecessarily with the subject. Mr. Tait positively asserts that electricity "as a method of *preventing* rupture is absurd." (Italics mine.) This is just where Mr. Tait shows his lack of "practical experience" on this point.

During the last fifteen years I have, through the kindness of professional friends, seen nearly a score of supposed extrauterine pregnancies, most of which I could not accept as such, and the subsequent history of which sustained my view. I have, however, personally treated five cases of undoubted extrauterine pregnancy, in which faradization successfully *arrested* the gestation and *prevented* rupture of the tube. In an additional case of collapse believed to be from rupture of the tube, faradism arrested the hemorrhage due to "torn placental vessels" and the lady recovered. This case I saw only *after* the rupture. Operation was peremptorily refused. The history was clear in the opinion of three physicians, two of whom were of large obstetric experience, and the result here was certainly not "a farce." Had the gestation been arrested sooner by electricity, severe hemorrhage from the placental vessels could not have occurred. The main object is to interfere in the earliest possible stage and before the placenta is much developed; hence, the fœtus *is* the source of danger. Destroy the fœtus, and the placental growth is stopped. I do not hesitate to say that in these cases the diagnosis was both correctly and easily made. The smallest tumor was as large as a walnut and in the other cases the tumor was somewhat larger; the signs of pregnancy were undoubted, yet the uterus was empty. We have in America obstetricians competent to diagnosticate extrauterine pregnancy, and this prior to rupture of the tube, for our women *do* suffer before that calamity overtakes them, and this could be verified did space permit reports. This kind of skill, though not so showy as operative work, yet has its place.

That faradization, properly employed, will destroy an ectopic pregnancy, and that galvanism will thereafter produce absorption of the then foreign body, is beyond cavil; and that fœticide is, in such cases, morally right and humane, because it is the only certain method of saving maternal life, cannot be honestly controverted, Mr. Tait's opinion to the contrary notwithstanding.

Very respectfully,

Wm. R. D. Blackwood, M.D.,
Neurologist and Electrician, Presbyterian Hospital.

Philadelphia, August 14, 1886.

NEWS ITEMS.

Surgeon-Generalship of the Army.—A special despatch to the *New York Tribune*, dated Washington, August 17, states that the retirement of Surgeon-General Murray of the Army, and the departure of President Cleveland before filling the vacancy, tend to make "Army politics" somewhat active. Under the law the President may select a surgeon-general from among all the officers of the medical corps of the army, which contains a large number of ambitious and able men. If seniority of rank and service should govern, of course Colonel J. H. Baxter, the Acting Surgeon-General, would succeed to the vacancy, but nearly a score of men whose names are lower on the list are active competitors for the place. Among them are Surgeon Sutherland, whose commission as colonel dates from 1876; Surgeon Bailey, whose colonel's commission bears the date of January 30, 1883; Colonel Glover Perin, Assistant Surgeon-General, whose commission dates from July 2, 1884, and who will reach the age for retirement on November 17, 1887, and Thomas A. McParlin, whose colonel's commission is dated September 10, 1875, and who will reach the age of sixty-four on July 16, 1889.

Among officers below the grade of colonel there are several candidates whose friends hope for their success. One of them is Lieutenant-Colonel Joseph R. Smith, who was appointed an assistant surgeon in 1854 and was promoted to the rank of full surgeon with the grade of major in 1862. His commission as lieutenant-colonel bears date January 9, 1885. Colonel Smith stands high in his corps and it is understood that influential friends are urging his promotion. Another officer who has strong backing is Surgeon Basil Norris, whose commission as lieutenant-colonel was issued December 14, 1882. The friends of Surgeon John S. Billings are pressing his claims with vigor. He received his commission as major in 1876. Besides the candidates above mentioned, there are Surgeons Page, Moore, McKee, Huntingdon, and several others, and it is probable that the delay in making the appointment will bring several more candidates forward by the time the President returns from his summer vacation. It is understood that the Secretary of War has recommended the promotion of acting Surgeon-General Baxter.

Professor Grashey of Würzburg has been called to Munich as the successor of the late lamented Professor von Gudden.

The Sixth International Congress of Hygiene and Demography will meet in Vienna, in September, 1887, instead of 1886, as originally proposed. Among other subjects the precautions, international or others, to be taken against the propagation of contagious diseases by rags; and the international regulations to be adopted against the adulteration of food products, will occupy prominent places in the discussions. Those who are interested are requested to suggest other subjects, addressing Prof. de Gruber, Brunn, near Vienna.

Dr. Wm. C. Dabney, of Charlottesville, Va., has been elected to the Chair of Practice of Medicine, Obstetrics, and Medical Jurisprudence, in the Medical Department of the University of Virginia.

THE AMERICAN DERMATOLOGICAL ASSOCIATION will hold its tenth annual meeting at Greenwich, Connecticut, on August 25, 26, 27. The president for this year is Dr. Edward Wigglesworth, of Boston.

THE LONDON HOSPITAL SUNDAY FUND amounts this year to over one hundred and eighty thousand dollars, being $25,000 more than it was last year.

SIR BALTHAZAR W. FOSTER.—The Queen, upon the recommendation of Mr. Gladstone, upon his retirement from office, has conferred the honor of knighthood upon Dr. B. W. Foster, President of the Council of the British Medical Association and late Member of Parliament for Chester.

DR. JAMES R. CHADWICK, of Boston, represented Harvard University at the Heidelberg Quinque-centennial.

A NOVEL PROFESSORSHIP is the establishment of a Chair of the Chemistry of Food in the University of Berlin. The incumbent will rank as professor extraordinary.

THE CHOLERA.—A cable dispatch from London, dated August 16th, says:

The Austro-Hungarian cholera returns for to-day are: Trieste, 16 new cases and 3 deaths; Flume, 3 new cases, no deaths. The Italian reports are: Barletta, 60 new cases, 30 deaths; Ruvo di Puglia, 21 new cases, 7 deaths; Bologna, 13 new cases, 5 deaths; Padua, 41 new cases, 4 deaths; Treviso, 18 new cases, 10 deaths; Verona, 6 new cases, 2 deaths; Legnago, 12 new cases, 3 deaths; Venice, 7 new cases, 2 deaths; Bisceglia, 13 new cases, 2 deaths; Acquaviva, 14 new cases, 3 deaths.

The geographical area affected by cholera exhibits the capricious behavior of this mysterious disease. Thus it is worst in Barletta, which is far away to the South, where the coast district between Monte Gargano and Brindisi is more or less affected. Thence it makes a clear leap of 300 miles to Lavenna and Bologna; then turns northward, extending, though in a less virulent form, throughout Venetia, including the island of Chioggia, and reaching as far east as Verona and as far north as Castel Franco, at the foot of the Alps. It is a noteworthy fact that the places most seriously threatened lie in the centre or on the edge of marshy plains formed by the alluvial deposits of rivers or the silting of the sea, which always induce more or less malaria at this season of year.

THE late DR. MOXON had a mind which habitually saw the humorous side of all things; every event and every statement seemed to be present to his mind in two aspects, and many of his sayings would be well worth preserving. His description of some of the aspects of the teetotal movement as "intemperate abstinence," and his definition of syphilis as "a fever diluted with time," are instances in point. As a teacher of materia medica, the shafts of his satire were frequently directed against inert drugs and obsolete formulæ; of elm-bark, for instance, he vouchsafed no further information than that the wood was "good for making coffins." His grave discussion of the motto of Guy's Hospital, "Dare quam accipere," whether it had not reference to the stock mixtures, not only raised laughter at the time, but served a useful purpose by drawing attention to the fact that some of these old-fashioned remedies were horribly nauseous, and probably not very active.

NOTES AND QUERIES.

POISONING BY OXALIC ACID USED LOCALLY.

A MEDICAL friend from the country has just informed me of a case which he was called upon to treat: a woman, who applied a quantity of oxalic acid, in substance, to the vagina, or os uteri, and when seen by the doctor she was suffering from both local and constitutional poisonous effects of the application. What would be the proper treatment in such a case? What would be the best remedies to eliminate the poison from the system?

L. C. H.

COLUMBUS, OHIO, August 12, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM AUGUST 10 TO AUGUST 16, 1886.

MAGRUDER, DAVID L., *Lieutenant-Colonel.*—Promoted to Surgeon, with rank of Colonel, July 26, 1886, vice Brown, retired.

ALEXANDER, CHAS. F., *Major.*—Promoted to Surgeon, with rank of Lieutenant-Colonel, July 26, 1886, vice Magruder, promoted.

CRONKHITE, HENRY M., *Captain and Assistant Surgeon.*—To be Surgeon, with the rank of Major, July 26, 1886, vice Alexander, promoted.

WALKER, FREEMAN V., of Georgia.—Appointed Assistant Surgeon, July 27, 1886, vice Cronkhite, promoted.

STERNBERG, GEO. M., *Major and Surgeon.*—Granted leave of absence for fifteen days.—*S. O. 186, A. G. O.*, August 12, 1886.

TREMAINE, W. S., *Major and Surgeon.*—Sick leave further extended six months.—*S. O. 187, A. G. O.*, August 13, 1886.

HOPKINS, W. E., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort Lowell, Arizona Territory, to Angel Island, California, for duty as Post Surgeon.—*S. O. 61, Division of the Pacific*, August 6, 1886.

MASON, CHAS. F., *First Lieutenant and Assistant Surgeon* (recently appointed).—To report by letter to the Commanding General of the Department of the East for assignment to duty.—*S. O. 187, A. G. O.*, August 13, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 14, 1886.

WALTON, THOMAS C., *Surgeon.*—To remain on present duty until September 1, 1886.

WHITE, C. H., *Surgeon.*—To remain on present duty until August 21, 1887.

RUSH, C. W., *Passed Assistant Surgeon.*—Authorized to delay ten days, under orders to Sitka, Alaska.

LUMSDEN, G. P., *Passed Assistant Surgeon.*—Ordered to hospital, Mare Island, California.

BALDWIN, L. B., *Passed Assistant Surgeon.*—Ordered to the U. S. S. "Ranger."

NEILSON, J. L., *Surgeon.*—Detached from the U. S. S. "Ranger," proceed home and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE-HOSPITAL SERVICE, FOR THE WEEK ENDING AUGUST 14, 1886.

CARTER, H. R., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, August 12, 1886.

GLENMAN, A. H., *Assistant Surgeon.*—Granted leave of absence for thirty days, August 9, 1886. To examination for promotion, August 12, 1886.

PETTUS, W. J., *Assistant Surgeon.*—When relieved at Savannah, Ga., to rejoin station at New Orleans, August 13, 1886.

ORIGINAL LECTURES.

SURGICAL LESIONS OF THE BRAIN AND ITS ENVELOPES.

A Lecture delivered at the College of Physicians and Surgeons, Chicago, Ill.

BY NICHOLAS SENN, M.D.,

OF MILWAUKEE, PROFESSOR OF PRINCIPLES AND PRACTICE OF SURGERY AND OF CLINICAL SURGERY IN THE COLLEGE.

GENTLEMEN: I shall call your attention to-day to an extremely important subject, the surgical diseases of the brain and its envelopes—lesions attributable directly to traumatism and the consecutive lesions following injury to the skull, the brain, and its envelopes. You will recognize the importance of secondary lesions of the envelopes if I call your attention to the fact that any lesion of the meninges is liable to extend to the brain substance proper by continuity of the inflammatory process, or may prove fatal by compression of the brain by the products of inflammation, which takes place on account of the unyielding character of the cranial vault. I wish you to remember that wounds of the brain, both incised and contused, may heal and cicatrize in a manner similar to that noted after injuries of other organs; in this respect we differ with the older authorities, who believed that injuries of the brain substance proper were incapable of repair; a loss of continuity in the brain substance proper which does not suspend an essential function may be followed by cicatrization and complete repair, and the organ may be restored to its functional integrity, provided, however, that the injury is unattended by consecutive traumatic infection, and consequently unattended by secondary inflammatory lesions; in other words, the loss of substance is replaced by a reconstructive process from the normal histological elements of the brain initiated by the traumatism.

About thirty years ago an eminent German physiologist (Wagner) made a series of experiments to ascertain the capacity of the brain to repair itself, and with another view to ascertain the physiological function of different portions of the brain. He found on removing sections of different portions of the organ that the operation, as a rule, was not followed by a process of destructive inflammation—that cicatrization was established in the same manner as when the injury is inflicted upon some other organ of less physiological importance. He not only found that wounds of the brain healed, but at the point of injury loss of brain substance was liable to occur as a result of consecutive cicatricial contraction without causing serious functional impairment. He ascertained this fact by a series of experiments, weighing different portions of the brain before and after the injury so accurately as to find the fraction of a milligramme of difference. Again, you will remember the classical case reported by Bigelow, of Boston, in 1855, where a crowbar passed through the brain substance, entering the skull from below upward, producing not only a great loss of brain substance, but contusion of the adjacent portions—a condition which must of necessity result in extensive cicatricial contraction during the reparative process. If, as was here the case, no loss of function occurred after the wound had healed, you can readily imagine that even an extensive loss of brain tissue does not necessarily interfere with the normal physiological functions of the brain if the injury is not followed by a secondary destructive process.

In introducing the subject of surgical lesions of the brain as they follow injuries of the cranium or its contents, it is necessary for a moment to direct your attention to those rare affections which occasionally follow incomplete fractures of the skull. By such an injury I mean a contusion affecting the cancellated structure between the external and internal table of the cranial bones; an indentation of one or more of the cranial bones by external violence, which is subsequently restored by means of the elasticity of the bones, assisted by the intracranial pressure, but resulting in compression of the cancellated tissue between the tables. It is a form of incomplete fracture as we observe it in the skull, the result of compression, which produces a condensation of the cancellated tissue, but does not affect the external or the internal table, an injury not recognizable by external signs, because the external table is smooth, while the internal table has a sufficient amount of elasticity to restore the normal relation of the parts though the diploë be crushed. It is a partial crushing of the diploëic structure, the result of force applied from without, as I have previously informed you, and which may temporarily indent the skull to the extent of even half an inch without producing fracture of the compact layers of the bone. This variety of fracture can only be recognized by evidences resulting from extravasation of blood, and ecchymosis at the point of injury, and by the immediate effects of the injury upon the functions of the brain. Its existence is also suggested a certain length of time after the injury has been received by a consecutive formative periostitis—a periostitis induced directly by the traumatism, resulting in the production of new bone, provided no infection has taken place at the seat of injury.

It is important to remember this form of injury from the fact that occasionally we meet with cases of injury of the cranial bones subsequently followed by serious brain disease, the secondary brain lesion being the direct result of the local injury in the diploë; an injury producing, in the first place, a laceration of the small veins in the diploë followed by thrombosis, the thrombus acting as a favorable culture soil for germs that may be accidentally introduced from a slight abrasion, resulting in an osteomyelitis—the osteomyelitis, again, extending by means of the consecutive thrombophlebitis to the subjacent meninges and to the brain itself. These remarks should teach you simply this fact: that all in-

juries of the skull, even when apparently slight, should put you on your guard with reference to the management of the case. Even a comparatively slight contusion of the cranial vault may be followed by a complexus of symptoms indicative of a grave central lesion. It is on this account that such injuries, slight as they may appear, should receive most careful treatment. This should have for its aim the prevention of secondary lesions; consequently, it must be directed toward the prevention of the inflammatory processes in the bone, and their extension to the brain and its envelopes. Rest in the elevated position, and cold applications are the measures upon which you rely, in the first place, to prevent an undue local inflammation, and if evidences of osteomyelitis appear, as evidenced by the appearance of fever, pain at the seat of injury, local œdema, then resort to early operative measures to reach the inflammatory focus, etc., before the infective thrombophlebitis has had time to extend to the subjacent brain tissue.

In speaking of traumatic meningitis, it is necessary to recognize two distinct varieties, the primary and the secondary. The classification introduced as early as the time of Ambrose Paré, and since recognized by all surgical authors, is this: A primary meningitis is that which is produced directly by traumatism following an injury within twenty-four to seventy-two hours; a secondary meningitis, on the other hand, is an inflammation of the meninges occurring an indefinite period of time after the local injury, but where the primary injury bears a direct etiological relation to the secondary lesion. When I call your attention to the causes which produce these two varieties, the distinction will appear plain to you. By a primary meningitis, I mean that form which results directly from an absorption of the products of putrefaction at the point of injury; a meningitis following a compound fracture of the skull, for instance, exposing the dura mater directly to infection. If the dura mater is exposed directly to the products of putrefaction, the septic germs penetrate the substance of the meninx proper, and the inflammation extends in a central direction *pari passu* with the invasion of the primary cause. The process begins at the point of injury, extends in all directions from a common central point toward the circumference, and in a central direction, by continuity and contiguity. By extension by continuity, I mean that the infective principle pervades the tissues of the dura mater, extending deeper and deeper, involving the subjacent envelopes, the arachnoid, and pia mater, and producing an inflammatory process in these membranes resembling in every respect the character of the inflammation in the dura mater, constituting the lepto-meningitis of recent pathologists. Again, extension takes place by contiguity of tissue, the pia mater being in close contact with the cortical layer of the brain the process extends from the meninges to the brain, so that we have a meningitis involving all of the meninges accompanied with an encephalitis, or a meningo-encephalitis, meaning an inflammation of all the meninges of the brain with inflammation of the subjacent brain tissue. Consequently, we again assert that, as in any other locality, a destructive inflammation of the meninges of the brain and the subjacent brain tissue following an injury is always to be considered as a direct result of traumatic infection or traumatism combined with infection from some antecedent pathological product. *No infection, no meningitis. No infection, no encephalitis.*

By a primary meningitis, then, we mean that which is induced by primary infection. This is important in a practical sense, inasmuch as it will again remind you of the importance of resorting to thorough local disinfection in all cases of compound fracture of the skull in order to obviate a consecutive meningitis. It should impress upon you again the fact that when a fracture is once compound you necessarily make it more compound in the attempt to secure free drainage. If you have an indented fracture which will not permit of free drainage between the fragments, it is necessary to expose the meninges by removing portions of the detached bone, and if the bone is not detached, you should enlarge the opening by means of a bone forceps or chisel, not only for the purpose of resorting to thorough primary disinfection underneath the fractured bone, but also for the purpose of insuring free drainage subsequently. We observe the same rule in these instances as we do in all other serous cavities. An infective agent, once introduced, is beyond our control if it has permeated the tissues beneath; consequently, the larger the opening the freer the drainage; the better the access to the infected district, for the application of disinfecting agents, the better the results.

By a secondary meningitis of a traumatic origin, I mean that which may follow an injury of the skull or the superimposed soft tissues at some indefinite subsequent time.

Premising, again, that, as in cases of primary meningitis, the secondary form is due to the same infective cause, but that the infection has remained for a certain time latent, local, and has extended subsequently by the development of certain well-defined, local, pathological conditions—as, for instance, suppurative osteomyelitis, a condition to which I have previously alluded in cases of contusion of the cranial bones, as being the result of the introduction of specific germs which we have learned produce suppurative inflammation. This condition may not be apparent at first, but gradually, as the disease proceeds, it involves the adjacent veins, producing a thrombophlebitis in the diploë, the thrombus growing in a central direction until it reaches the meninges, where a similar suppurative process is initiated as at the primary seat of infection. It is a suppurative meningitis when the lesion is caused by the extension of suppurative inflammation from the exterior or as the result of a purulent thrombophlebitis. But the specific cause may have affected one of the large venous channels within the cranial vault producing a primary sinus-phlebitis, and the meningitis may be due to extension from this source. By this I mean an inflammation of the large venous sinuses in the cranial cavity, the result of extension of the inflammatory process from the local injury to a subjacent sinus. In considering this part of our subject you must remember the direct communication that exists between the external veins of the skull and diploë and the sinuses through the medium of connecting venous channels. If, for instance, we find we have to deal with only a local inflammation of an infective type, a furuncle, a suppurating wound of the soft parts, or an anthrax, and no fracture has existed, but a local infection has taken place in the soft tissues; if from this focus of infection a thrombophle-

bitis take place, the thrombus forms in the vein, growing by aggregation in a central direction, and gradually reaches the sinus, a thrombus is formed in the sinus, and its presence provokes an inflammation in the sinus itself producing a sinus-phlebitis. By direct contact with the sinus of the meninges the inflammation extends in all directions, producing an infective meningitis resembling, in its character and results, in every respect the primary inflammation in the sinus and in the superficial veins. Furthermore, the infection may have a still deeper origin, and may extend in a peripheral instead of in a central direction; in other words, the inflammatory primary disease may originate within the brain, the process affecting the meningeal membranes from the centre of the brain in a peripheral direction, hence a consecutive meningitis, following a primary encephalitis terminating in an encephalo-meningitis.

In alluding to the symptomatology of traumatic meningitis, the first symptom you will observe is a changed condition of the mind of the patient; a psychical perturbation due to hyperæmia of the superficial cortical substance of the brain, as this portion of the brain is predisposed by the anatomical arrangement of its structure to extension of the inflammatory process from the meninges. The perverted sensorium points to an increased, exaggerated physiological function as the result of increased tissue changes in the gray matter of the cortex, due to an increased vascularization of that portion of the brain, producing increased exaltation of the psychical functions of the brain. If you are called upon to treat this disease as we occasionally meet with it—after a compound fracture of the skull, for instance—the first thing you will notice on your visit is that your patient is contrary, peevish, morose; complains of every little thing; the least noise produces painful sensations. As the disease progresses, or as long as this exaltation in the psychical function of the brain increases, delirium follows—delirium sometimes of an active character; the patient even attempts to run away, jump out of the window, etc.; consequently, any serious change pointing toward a perverted sensorium in cases of compound fracture of the skull should receive your earnest and early attention. One of the first positive evidences of the existence of traumatic meningitis is an excruciating headache, referable at first to the primary seat of the inflammation, but as the process extends it becomes more diffuse. It is a headache which it is difficult to describe, but the words "excruciating" and "diffuse" are sufficient to indicate the character and extent of the local inflammation. It is a pain resulting from inflammation of a serous membrane dense in structure—a pain resulting from vascular engorgement and increased intracranial pressure. As a result of increased exaltation of the cerebral functions we very frequently observe convulsions; the area of peripheral irritation results in exaggeration of the motor function—convulsions general or local, as the case may be. If only one side of the brain is affected, the process is yet limited; in all probability the convulsive movements will occur on the opposite side. Again, if the process is limited to a particular sphere, involving the nerves supplying certain definite muscular groups, you observe a monospasm in the group of muscles supplied by the nerves which are irritated by the central disease.

Vomiting is an early symptom, and when persistent denotes an acute and severe attack. Persistent vomiting, in the absence of mechanical obstruction or inflammatory affections of the digestive tract, should always awaken suspicion of the existence of cerebral disease. Cerebral vomiting is not the retching due to a disturbance of the digestive function, but a mechanical vomiting, so that in the absence of gastric disturbance, and the rapidity with which the attacks occur, you may suspect a central cause. The pulse, in the beginning of the disease, is always increased in frequency, say from 80 to 120, full and bounding, until the local disturbance has led to an increase in intracranial pressure, when it becomes slow, indicating in this connection compression of the brain. By a slow pulse I mean one that varies from 50 to 60 beats per minute. After a few days it again becomes rapid and feeble, being simply the forerunner of approaching dissolution, indicating a general paralysis, due to the central cause; although at first rapid, it has a natural tendency to become softer and smaller in volume, consequently the slowness following a rapid pulse is not a favorable, but a serious change. When it becomes more rapid and small, it is an indication that general paresis is occurring as one of the results of cerebral compression.

The temperature in meningitis is always increased—usually 100° to 104° F.—the temperature usually can be considered as an index of the intensity and extent of the infection. As in all other infectious traumatic diseases, an early high rise in temperature forebodes danger. It simply means that the infection has taken place rapidly and has become diffuse; that the local process has extended with great rapidity, involving at an early date a large surface of the meningeal structures. A paresis in cases of meningitis is always the result of secondary pathological changes produced by the local inflammation; by this I mean either an increase in intracranial pressure, resulting in cerebral compression and consequently a localized area of anæmia in the brain, or an extension of the inflammatory process to the brain and destruction of the centre of sensation or motion, as the case may be; a paralysis first localized, extending as the local cause spreads, affecting more distant structures; a paralysis indicating simply the extent of the cerebral injury or disease, primary or secondary, according to the pathological condition which characterizes the case. The pupils in meningitis are first, as a rule, contracted; in a few days they may be normal, but on testing their contractility you will alway notice a slow response to light, which is one of the characteristic features of meningeal inflammation. As the disease progresses, and exudation takes place, and compression is produced, one pupil may be dilated and the other contracted. When cerebral compression is well marked, dilatation of both pupils takes place.

By pyæmia as a complication of traumatic meningitis, we understand the existence of distant or metastatic abscesses, resulting from disintegration of a thrombus in the sinus, or in the veins.

We have now arrived at an important pathological consideration of cerebral pathology. Strange as it may appear, ancient authorities have entertained the most diverse opinions in regard to the relations existing between a local suppuration and distant abscesses. For instance, the distinguished pathologist, Bichat, claimed

the existence of a peculiar sympathy between the brain and the liver; a sympathy which would come into activity in case of pathological conditions in the brain, producing similar conditions in the liver. Another writer claims that metastatic abscess of the liver is frequently a concomitant condition in cases of pyæmia from cerebral suppuration, and that the disease is first located in the liver, and subsequently extends from it to the brain. Recent pathological research has demonstrated that pyæmia in thrombophlebitis or sinus-phlebitis constitutes one of its greatest dangers, and on post-mortem examinations is found as one of the most frequent causes of death; the thrombus by disintegration will produce pyæmia just as when a thrombus forms in any other part of the body under similar circumstances, giving rise to embolism and metastatic abscesses. In cases of suppurative inflammation of the brain and its envelopes, the process is facilitated by the direct communication of the large reservoirs of the brain with the jugular veins, so that pyæmia as we observe it in cases of thrombophlebitis or sinus-phlebitis means simply the coexistence of metastatic abscesses caused by embolism from disintegration of the infected thrombus.

In the differential diagnosis we must take into consideration concussion. Concussion may precede meningitis, and may complicate the clinical picture. Concussion following immediately after an injury, produces symptoms not referable to any particular portion of the brain, but a condition in the entire cerebrum resulting in partial suspension for the time being of its physiological functions; consequently, during the first twenty-four or forty-eight hours it is impossible to make a positive differential diagnosis. If, however, the symptoms prove more permanent; if concussion is followed by meningitis, there is no restoration of function *ad integrum*, as in uncomplicated cases of concussion, but the process proceeds and results in the manifestation of focal symptoms. Traumatic meningitis is distinguished from incipient encephalitis by the absence of symptoms indicating central irritation—symptoms expressive of exaltation of the cerebral functions, if the inflammatory process in the brain is not complicated by meningitis from the beginning. Again, encephalitis, at first primary and localized, gives rise to early focal symptoms; that is to say, symptoms pointing toward a distinct portion of the brain as the seat of the lesion. The local injury, if unattended by meningitis, again gives rise to focal symptoms from the very beginning, localizing the lesion in the brain, and an absence of those severe symptoms pointing to cerebral irritation, as we observe it in meningitis.

Abscess in the brain has quite a different clinical history: contusion, thrombophlebitis, sinus-phlebitis, cranial osteomyelitis preceding the formation of pus in the brain; it is also attended by focal symptoms, as evidenced by circumscribed regions of paralysis of certain definite muscular groups, pointing to the local lesion in the brain as the cause of the paralysis. Again, abscess of the brain is not attended by such a constant rise in temperature as is found in cases of traumatic meningitis—in fact, in many of the cases recorded the temperature has been noted as being subnormal.

It is impossible, in the beginning, to differentiate simple congestion from inflammation, inasmuch as inflammation is always preceded by congestion; but congestion independent of inflammation is only a temporary condition yielding to local or general measures.

In regard to the localization of the primary lesion a great deal has been said and written.

Bergmann made an attempt to differentiate between convex meningitis and basilar meningitis, and the result of his observations appears to prove that a convex meningitis is noted particularly for its acuity; for its rapid extension and the intensity of symptoms. It has also been claimed as a distinguishing feature that in cases of convex meningitis paralysis appears sooner and is more extensive. Basilar meningitis, on the other hand, is noted for the slowness of the local process, the absence of intense symptoms due to cortical irritation; circumscribed paralysis appearing at a late stage; again, it differs from meningitis of the convex surface of the brain by a tendency of the inflammation to extend along the spinal structures, being followed by a spinal meningitis, as indicated by rigidity of the muscles of the spine and neck, the disease resembling in this respect, in many instances, cerebro-spinal meningitis.

The prognosis has not yet been considered. It is sufficient to say that it is always grave; the majority of cases of traumatic infective meningitis prove fatal. The prognosis is always unfavorable because the infection once thoroughly established is beyond the control of the surgeon; the process always manifests an inherent tendency to extend to all of the membranes and the subjacent brain tissue, and even to the contents of the spinal canal. The prognosis is grave because traumatic meningitis means a suppurative meningitis; suppuration necessarily follows from the very nature of the primary infective cause, provided that life is sufficiently prolonged for such a termination to take place, because in many instances death is produced earlier by compression on account of the unyielding character of the cranial vault, resulting in fatal compression of the brain which annihilates the essential physiological functions of the brain.

In the treatment we will briefly refer to the importance of establishing free drainage as a prophylactic measure; and the resort to all measures which are known to effect thorough local disinfection. It has been found, for instance, that it is not injurious to apply even caustics to the brain, so you are justified in cases of suspected infection after an injury to resort to local disinfection by thoroughly cleansing the wound and its vicinity, to be followed by the application of a ten per cent. solution of chloride of zinc to the wounded surfaces, and thorough and prolonged irrigation with a one-tenth per cent. sublimate solution—taking special precautions that these agents must be brought in contact with the entire surface which has been exposed to infection. The prophylactic treatment is of the greatest importance, while the curative is by general consent considered as *nil*. The life of the patient in all cases of compound fracture is, as it were, in your own hands. If the inflammation has taken place at the seat of traumatism before the patient has come under your care, the most conscientious application of all antiseptic precautions is called for in all cases of wounds of the scalp and compound fractures of the skull, as furnishing the only guarantee against traumatic meningitis. The case is usually beyond hope of recovery after the infective inflammation has invaded the subjacent meninges. In a recent

case before you touch the wound you must disinfect your hands with a strong solution of sublimate. To ascertain the extent of the injury, expose the upper portion of the wound by incising the scalp freely, and if there is any doubt as to the aseptic condition of the exposed meninx, you should disinfect it, being careful, at the same time, to arrest all hemorrhage, so that the formation of a subsequent blood-clot may not act as a favorable culture soil for any remaining germs. Prevent the accumulation of wound products by establishing free drainage of the subcranial space.

The old-time remedy, venesection, needs to be mentioned, not as a curative measure, but as a potent prophylactic remedy to modify reaction after an injury to the brain. When you are dealing with a case of contusion or concussion of the brain—injuries which are necessarily followed by a certain amount of reaction, if you can select the time when reaction is to be reëstablished to modify intravascular pressure, you may prevent undue engorgement by the use of timely and well-directed measures; consequently, at that stage, when cerebral irritation manifests itself by severe headache with a bounding pulse, if there are no contraindications, you are fully justified in resorting to the free use of the lancet as the most potent agent until you have brought the heart's action under your control. With a view of still further modifying the intracranial circulation, resort early to prolonged use of applications of ice to the head, which is particularly useful in this locality, because the vessels being located so near the surface, the ice has a direct effect in contracting the smaller vessels, thus diminishing in direct manner the blood supply to the brain. This agent is not only effectual in modifying the circulation, but at the same time it has a prompt effect in reducing the temperature. The prolonged application of cold may also produce a salutary effect by arresting or retarding the reproduction of infective germs. Albert has well said that in all cases of injury to the skull and brain, you are expected to do something. He says there is no harm in the application of cold water, but when inflammation is threatened, it should always give way to the application of an ice-bag as one of the most potent means to meet the urgent indications. The beneficial effects of cold in modifying the cerebral circulation, in diminishing symptoms of central irritation are well known, and should never be omitted in the prophylactic and curative treatment of traumatic meningitis. In all cases of wound infective diseases we should aid the efforts of nature to eliminate infective germs by inducing an artificial gastro-intestinal catarrh, and for this purpose it is advisable to administer a large dose of calomel with the view of limiting also the cerebral congestion by inducing an artificial congestion in the alimentary canal.

I will next call your attention to the frequency of suppurative inflammation of the brain and its envelopes caused by preëxisting pathological processes independently of traumatism. In cases of suppurative osteomyelitis of the mastoid process, the vein which merges into the lateral sinus is often the medium of a direct extension of inflammation to the lateral sinus, the primary cause extending along that vessel by continuity and involving finally the sinus itself. It is that form of sinus-thrombosis and sinus-phlebitis that so frequently proves fatal in cases of inflammation of the internal ear and mastoid cells, producing, as a result, suppurative meningitis, abscess of the brain, and pyæmia. Suppurative inflammation in the interior of the cranium has also not infrequently been observed as the result of caries of the cranial vault, taking place in a similar manner by continuity of the inflammatory process along the veins, extending, perhaps, to the longitudinal sinus, resulting in a sinus-thrombosis, sinus-phlebitis, and finally meningitis. The succession of pathological changes may, however, be the reverse, the process in the meninges extending by continuity of tissue directly to the sinus, producing sinus-phlebitis, which is in turn again followed by a sinus thrombosis. The symptoms indicating this lesion are those directly referable to a disturbance in the cerebral circulation. If a sinus has become suddenly obliterated either by extension of the thrombus to the sinus, or as a result of secondary sinus-thrombosis following sinus-phlebitis, a passive congestion on the venous side of the obstruction is a necessary and inevitable result; consequently there are symptoms indicative of cerebral congestion and fulness of the external veins which are contributory to the obliterated vessel. When the longitudinal sinus is the seat of obstruction, the veins of the forehead become distended; in case of sinus thrombosis of the lateral sinus, we observe dilatation of the vein over the mastoid process which perforates the bone and empties into the lateral sinus; obstruction in this particular vein being indicated *intra vitam* by local œdema in the region of the mastoid process. Please remember the fact that in case of sinus-thrombosis of the lateral sinus, following suppurative inflammation of the ear, one of the first evidences pointing to obstruction of the venous return from the lateral sinus is local œdema in the region of the mastoid process, and which is not attended by any evidences of superficial inflammation. Again, in case of sinus-thrombosis of the cavernous sinus an interference with the return of venous blood from the orbital region takes place, indicated by an unusual prominence of the eyeballs, but as in this particular region the venous engorgement affects by its close proximity the nerves supplying the eye— the oculomotorius—you have, in addition, evidences of motor paralysis affecting the muscles of the eye. In thrombosis of the lateral sinus, when the thrombus increases in length in a central direction and reaches the jugular vein, the return of venous blood through this channel is obstructed. Gerhart says "this lesion is indicated by a preternatural emptiness of the external jugular vein on the affected side, due to a more easy return of the venous blood through the partially empty internal jugular." You will recognize the lesion by comparing the external jugular veins, locating the lesion on the side presenting a preternatural emptiness or collapsed condition of the vein. If, with this collapsed condition you have symptoms indicating a primary suppuration in the internal ear; and if at the same time you also have symptoms expressive of cerebral congestion, your diagnosis is almost positive: a thrombus in the lateral sinus.

In regard to the prognosis, just one word. If a sinus-thrombosis results from a direct injury to the sinus independently of traumatic infection, simply as the result of anatomical imperfection in the sinus itself arising from the traumatism, interfering with the circulation in the vessel, and the thrombosis is followed by a productive

sinus-phlebitis, your prognosis is favorable, as a gradual obliteration of the sinus is not incompatible with a normal performance of the functions of the brain. If, on the other hand, a thrombus has occurred as the result of a suppurative sinus-phlebitis, or from infection from any other source, the thrombus does not become adherent; it does not serve as a medium in which the products of plastic proliferation find a favorable soil for growth and development, but it is an infective thrombus, and as a result of that infection disintegration takes place, the thrombus breaks up, and produces embolism and pyæmia. Consequently in all cases of infective sinus-thrombosis and infective sinus-phlebitis, the result of infection either from osteomyelitis or wound infection, your prognosis must be guarded, as a fatal termination is inevitable.

In regard to treatment there is but little to say, inasmuch as most of these sinuses are not within reach of operative procedure. It has been suggested in the case of suppurative sinus-phlebitis of the superior longitudinal sinus to expose the sinus in order to remove the infected thrombus, with a view to prevent an extension of the infection to subjacent parts and to guard against pyæmia; but if you recollect the extent to which some of these channels may be blocked the measure appears hazardous to say the least. The inaccessibility of the cavernous sinus, and the importance of the structures in the immediate vicinity of the lateral sinus also preclude the advisability of operative interference. You will treat these cases, then, on the same principle as you would pyæmia. The most important element is the prophylactic treatment. In cases of suppurative inflammation of the mastoid cells do not postpone an operation until sinus-thrombosis has taken place, but resort to timely treatment by using the chisel to gain access to the infected structures, remove the infected tissues by *evidement* and ignipuncture, effect complete and thorough disinfection, and treat the wound as an infective one. These are the measures, when timely resorted to, which will prevent sinus-thrombosis in cases of suppurative inflammation of the cancellated tissue of the mastoid process. The same treatment should be adopted in all osteomyelitic processes wherever they involve the cranial bones.

Concussion.—We will next briefly consider the subject of concussion. By concussion of the brain I mean a sudden and complete annihilation of cerebral function as the result of an external application of force unattended by any recognizable anatomical tissue lesion. It is a perverted functional condition of the brain which results from a sudden application of force, producing a jar, as it were, of the brain substance, a condition which cannot be demonstrated in the brain, either microscopically or macroscopically; its essential feature consists in an altered relation between the molecular component parts of the brain, produced by a sudden commotion or jar. The complexus of symptoms which characterize this lesion appears immediately after an injury, and are expressed to us, in the first place, by a total loss of consciousness; the patient does not appear to recognize his condition; is totally ignorant of what has happened. Very soon after the accident he vomits, which appears as a mechanical act—it is not the kind of vomiting observed in cases of traumatic meningitis, but simply the evacuation of the contents of the stomach, which is undoubtedly an effort on the part of nature to restore the equilibrium of a disturbed circulation. The pulse is slow, from 50–60 per minute, soft and compressible. A peripheral paresis of the vasomotor system is indicated by extreme paleness of the cutaneous and mucous surfaces, clammy perspiration; respiration almost imperceptible; the respiratory movements being limited, imperfect, and slow. Acute cerebral anæmia following immediately upon concussion is indicated by an equal dilatation of the pupil; the paralysis, being partial and general, does not affect any particular muscular group, but all the voluntary muscles, the nerves of motion and sensation, as indicated by a depression of all of the cerebral functions; in other words, the prominent clinical features of concussion are: unconsciousness; slow pulse; slow respiration; dilated pupils, with paresis of the sensory and motor nerves.

In making a differential diagnosis the only conditions which might lead to difficulty are the existence of contusion and compression. Concussion and contusion have been erroneously used as synonymous terms, but constitute two well-marked and distinct lesions, both from a pathological and prognostic standpoint. Concussion is usually an evanescent condition, not attended by any appreciable structural changes, while contusion signifies a laceration of the brain substance and some of the smaller bloodvessels, attended by extravasation of blood, followed by symptoms pointing toward a localized lesion in the brain. Difficulty in diagnosis arises from the fact that contusion is always attended by concussion; and the symptoms of concussion from the commencement may overshadow those due to the contusion. A differential diagnosis is only possible after the symptoms pointing toward concussion have disappeared. Compression due to traumatism, for instance after a depressed fracture of the skull, produces suddenly a diminution of space within the cranial cavity, and, if considerable, is almost sure to be attended by focal symptoms indicating compression of the brain. While the symptoms of concussion almost always subside within a few hours—or, at the most, within a day or two—the symptoms pointing to contusion or compression remain for a longer time, indicating a more serious injury to the brain.

In the treatment of concussion the most that is needed is physiological rest, absolute and complete, in the recumbent position, as this position favors a restoration of the disturbed circulation to its normal condition. If symptoms indicative of shock accompanying concussion present themselves, you may administer stimulants sufficient to counterbalance the depressing effect of the traumatism, favoring at the same time peripheral circulation in the extremities by the application of external heat. The older English surgeons always resorted to repeated bleeding in cases of concussion, with a view to prevent subsequent inflammation. It is not necessary to state the result, perhaps, but a great many patients died, not from the concussion, but from the repeated venesections. Concussion uncomplicated by other lesions is only a temporary condition, and in the great majority of cases yields readily to nature's resources, consequently all that is necessary is to secure rest, and to rely on an expectant course of treatment; at the same time it is your duty to keep your patient under the closest observation until you have excluded the possibility of deeper and graver brain lesions.

One of the first symptoms frequently observed in cases of cerebral contusion are convulsions, local or general, according to the extent and location of the contusion. If the convulsive movements assume the form of a monospasm, the injury is usually located on the opposite side of the brain. Let me here call your attention to the fact that contusion does not necessarily occur always at the site of the external injury. If, for instance, the force has been applied to the right side of the head, and the paralysis or convulsive movements occur on the same side, it is evident that the transmission of force through the brain substance has resulted in contusion of the brain on the opposite (left) side. This is an extremely important point to remember, when we consider the causative relation between a contusion of the brain and brain abscess, where it is of the greatest importance to localize with accuracy the seat of the lesion. It is a familiar fact that surgeons have often been disappointed in seeking for pus on the injured side in operations for abscess of the brain, when perhaps by transmission of force the contusion and subsequently the abscess have occurred on the opposite side.

In conclusion, let me again impress upon your minds the importance of treating even the most insignificant wounds of the scalp under the strictest antiseptic precautions, with a view of securing for your patients absolute protection against the disastrous consequences arising from traumatic infection. In cases of contusion of the brain make an early diagnosis and adopt timely measures which will prevent undue vascular engorgement, and, to a certain extent, extravasation at the point of contusion. In concussion of the brain be careful to eliminate the existence of contusion by watching the course of the lesion diligently until a sufficient time has elapsed, when a positive differential diagnosis between concussion and contusion can be made; and after you have fully satisfied yourself that you are dealing with a case of concussion complicated by contusion, adopt measures which will prevent microbic invasion of the contused area, and which will, at the same time, moderate the vascular engorgement at the seat of contusion.

ORIGINAL ARTICLES.

THE DETECTION OF CHRONIC BRIGHT'S DISEASE.

By CHARLES W. DULLES, M.D.,

SURGEON TO OUTPATIENTS IN THE HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA, AND IN THE PRESBYTERIAN HOSPITAL IN PHILADELPHIA.

In January, 1884, a gentleman came to consult me on account of a sense of constriction and oppression which he felt in the lower zone of the thorax, and some dyspnœa, which affected him chiefly when he walked in the morning to the car which conveyed him to the place where he exercised his duties. He was a man with important responsibilities, past middle life, rather stout, of medium height, of excellent habits, but whose duties interfered with his mid-day meal and required him to sit for five or six hours every day in a crowded and ill-ventilated room. The point in regard to his case to which I wish to call attention does not require further description of his condition and symptoms, except to say that he had never known of having any œdema of the feet or other cause to suspect his kidneys. On making a physical examination of his thoracic and abdominal organs, I found no sign of any disorder except a loud, ringing, or booming second sound of the heart, which my experience has led me to regard as of peculiar significance. This sound is simulated by that which is heard when one presses the palm of his hand pretty firmly against his own ear, and at the same time taps the back of his head with his forefinger. This sound, heard over the heart, has seemed to me to be characteristic of a moderate degree of essential hypertrophy of this organ. Hearing it in the case I am describing, I thought it important to examine the patient's urine. This I did most carefully and thoroughly. I found it normal in amount, color, clearness, sediment, and odor. Its reaction was strongly acid, its specific gravity 1.020; the urates were normal; uric acid was in excess; the phosphates were normal; no albumen was found, and no sugar. By a microscopical examination, after forty-eight hours settling, I found various forms of uric acid crystals, a few small plugs of small white cells, and a *very few delicate hyaline casts*. I gave my patient a cautiously worded diagnosis, advising careful living, and instituted treatment which relieved his symptoms. Becoming deeply concerned about himself, however, he now, with my full approbation, consulted the gentleman who had before been his medical adviser. The latter examined him, and said that his heart was perfectly healthy, and that an examination of his urine showed it to be normal. Not quite reassured by this, the gentleman consulted three other eminent medical men; one of whom said he had a fatty heart, while two of them said his heart was sound. One of the latter, who also said that his kidneys were perfectly healthy, had him under treatment for a long time, giving him chiefly Fowler's solution and nitroglycerine. A prolonged absence from work, with travel and carefully regulated diet, contributed to making the patient feel decidedly improved. After the lapse of two years and a half, he came to me again on July 3, 1886, asking me to examine his urine, so that he might select an appropriate medicinal spring, at which he should spend his summer vacation.

The circumstances which I have narrated made this visit one of peculiar interest to me, and the examination of the patient's urine equally interesting. Again I found the amount, color, clearness, and sediment normal, while the odor was not pleasant. The reaction was acid, and the specific gravity 1.024. The urates were normal, the phosphates were doubled. On testing by boiling the filtered urine, and by applying the nitric acid test in the ingenious manner suggested by Dr. Thomas S. K. Morton, in The Medical News, May 8, 1886, I failed to discover any evidence of the presence of albumen. But on testing it with the potassio-mercuric iodide and citric acid paper of Dr. Oliver, of Harrogate, England (with some papers which I received directly from him), I did find a distinct trace

of albumen.[1] I found no sugar in the urine, and no other abnormality except a slight excess of coloring matters. After twenty-four hours, and again after forty-eight hours, I made a microscopical examination, and found hyaline tube casts, one young epithelium cell, various forms of uric acid, oxalate of calcium crystals, and several varieties of microörganisms.

Fig. 1 represents what was found under a single cover glass, although all these objects were not seen in any one field of the microscope.

FIG. 1.

a. Hyaline tube casts—one so-called waxy cast.
b. Uric acid in various forms.
c. Young epithelium cells.
d. Oxalate of calcium.
e. Micrococci and bacilli.

It is seen, then, that what I discovered at this last examination corresponds with what I found two years and a half ago; and I think it corroborates the diagnosis I then made of chronic Bright's disease, associated with a moderate degree of essential hypertrophy of the heart, or *vice versa*.

The interest of this case hinges upon the diagnosis and the ground upon which it rested. As to the heart, the diagnosis rested upon the peculiar sound described above, which has never, I think, deceived me. But the diagnosis was, in my opinion, supported by what I found in the urine, and the inference which it warranted. The discovery of the tube casts, which escaped another, and perhaps several examiners, may have been due to the method of examination which I employ, and it is chiefly to call attention to this that the account of the present case is published.

In the first place, I am strongly impressed with the advantage of allowing the sedimentation of a specimen to take place in a straight glass, and not in a conical one, as is recommended in most of the books. In the latter, I think, one may easily miss a few tube casts, because they are not heavy enough to resist the attraction and friction of the sides of a conical glass, and so never find their way to the bottom. For this purpose a test-tube with a foot, I think, is the best receptacle.

Another point to which I desire to call attention is the plan I have devised for catching a specimen of sediment for microscopical examination when the deposit is very slight. The apparatus I use is represented in Fig. 2. After leaving the urine to settle

FIG 2.

in a test-tube with a foot for twenty-four hours, under a paper cover pressed down upon and around the top of the tube, I take a long, pointed glass tube, close the upper end firmly with my finger, and, pushing the point through the centre of the paper cover of the test-tube, thrust it steadily to the bottom of the urine. I now remove my finger, and the bottom layer of the urine, containing the deposit of twenty-four hours, flows up into the long tube. When it has risen to the level of the urine in the test-tube, I carefully twist a piece of soft paper over the upper end of the second tube, or stuff a small bit of absorbent cotton into it, to keep out all foreign substances, and allow the apparatus to stand undisturbed for twenty-four hours or longer, during which the deposit contained in the column of sediment falls to the bottom of the smaller tube. At the end of this time I close the upper end of the smaller tube firmly with a finger, withdraw it carefully from the test tube, and then allow the two or three drops nearest its point to run out on a slide, in two or three places, cover them properly with thin glass, and put them under the microscope.

[1] In this connection, I would refer those who are interested in the subject of delicate tests for albumen, to an interesting paper on this subject by Dr. James Tyson, and to the discussion upon it, before the Philadelphia County Medical Society, December 19, 1883, published in the volume of Proceedings for 1883–1884.

In this way, I believe, one may obtain a most typical specimen of the deposit, and I think the adoption of this method might prevent such a conflict of opinion as took place in the case I have described, or such an occurrence as is mentioned by Dr. Roberts in his work on *Urinary and Renal Diseases*, 4th edition, p. 439, in which he discovered hyaline casts in a urine which had been repeatedly examined with negative results by two medical men well accustomed to such examinations.

It is in the cases in which it is difficult to determine the existence of chronic Bright's disease that it is often most important to be aware of its presence. Many obscure symptoms become intelligible when this factor is recognized and taken into account, and it is often possible to put a patient on his guard against dangers which would not be considerable if the kidneys were in perfect condition. I am aware that there is often unnecessary alarm felt both by the patient and by his physician upon the discovery of a chronic disorder of the kidneys; and I would not like to contribute to any increase of the already exaggerated dread of Bright's disease. But if such a condition is present, it cannot be doubted that it would be for the advantage of both in most cases to have it known; and so I hope that the simple suggestion which I here make may prove of value.

4101 Walnut Street.

PSEUDO-INTESTINAL OBSTRUCTION.

By H. ILLOWAY, M.D.,
formerly resident physician in the cincinnati hospital.

In perusing the journals we find reported many cases of intestinal obstruction that seem to have presented but little difficulty in their treatment, and in which, after a shorter or longer interval, the patient goes on his way rejoicing. The main features of the majority of the cases so reported, seem to be the sudden constipation, the ineffectiveness of purgatives, and the rapid relief afforded by an enema or two. It is, then, not to be wondered at that when cases are met with that are more protracted, more stubborn, that are attended with more distressing manifestations, the practitioner, with the histories of the above-mentioned cases in his mind, should proceed slowly, abstain from all radical measures in the hope that the next prescription or the next clyster administered will bring about the much desired cure. Comparing these numerous cures with the statistical tables presented to us by Leichtenstern, Brinton, and Treves, we cannot but be struck by the discrepancy, and when we recall the aphorism of De Haen regarding this malady, "*morbus terribile creberrime lætale*," we certainly must be surprised.

The question then naturally arises, Are all these cases cases of intestinal obstruction, or may there not be some other cause for this sudden constipation and for the attendant manifestations?

To a certain extent this question has already received an affirmative reply. In 1865 Dr. Henrot, of Paris, published a monograph entitled *Des Pseudo-Étranglements*, in which he calls attention to a series of cases which, though having many of the symptoms of intestinal obstruction, were in reality not so; the manifestations being brought about by causes other than an obstruction of the bowel. In support of his position he cites numerous cases which, during life, presented all the symptoms of intestinal obstruction, but in which, upon post-mortem examination, the lumen of the bowel was found perfectly pervious.

In an elaborate study of the etiology of this new category he classifies these cases under three heads:

1. Those due to direct paralysis of a segment of the bowel from changes in its walls.

2. Those due to indirect paralysis, depending upon reflex nervous action.

3. Paralysis of the bowel as a feature in a general affection of the nervous system.

It can be readily seen from the above classification that it embraces many grave forms of disease which frequently end fatally, in which, during life, it is impossible to make a diagnosis between the real and the pseudo form of obstruction and in which only an autopsy can disclose the true condition. The milder forms are generally attended by such other phenomena as, *e. g.*, those of hysteria, so that their true character is, in a majority of instances, easily recognized.

A series of cases have, however, come under my observation, which, though belonging in the category of pseudo-intestinal obstruction, cannot be ranged under any of the etiological heads above mentioned—a class of cases which, having many of the features of intestinal obstruction, are frequently mistaken for such, are reported as cases of true intestinal obstruction cured with little difficulty, and are, without doubt, included in the statistics of recoveries from this malady.

The cases that I have seen, etiologically considered, may be classified under two heads:

1. Those due to paresis of the bowel from inhibition of the nervous centres—or, perhaps, but temporary inertia of the muscular intestinal coat.

2. Those due to large accumulation of flatus.

Case I.—In the summer of 1880, I was called to see, in consultation, Mr. A. L., a German, saloon-keeper, æt. forty-two, a man of ordinary stature and good physical development, who had been engaged in his present business for years. The history of the case, as given by the attending physician, was as follows: Patient being constipated for several days he took a purgative; this not producing the desired effect, he called upon his physician, who prescribed for him the Vienna laxative infusion, reinforced by an addition of sulphate of magnesia. This not acting, some other purgatives were prescribed and taken, but without any effect. The doctor now began to suspect that he had to deal with a case of intestinal obstruction. The patient complained of great fulness, and said he could not lie down; he had great difficulty in breathing; his countenance was very anxious. He dreaded that he was afflicted with some terrible malady, and was, perhaps, near his end, because his bowels would not act. He was extremely restless and could not lie still for five minutes at a time; he would lie down on the bed for a moment and jump up again and walk the floor. He had not slept at all for two nights; he did not complain particularly of pain. An ex-

amination of his abdomen revealed nothing upon the exterior to indicate an intestinal obstruction. There was some tympanites, not very extensive, and some sensitiveness to pressure over the whole abdominal region.

I advised an enema of hot water to be immediately administered. An ordinary rubber syringe was procured, and he was at once given an injection of about a pint and a half of water, at a temperature of 103°. In about ten minutes this was followed by another injection of about the same quantity of cold water, temperature about 90° F. These passed away. He was now ordered small doses of quiniæ sulphat. with extract of nux vomica. We left him, returned in about three hours, and gave him another injection of hot water, which was followed by a free fecal evacuation with discharge of flatus. He was ordered to continue the pills. On our visit the next morning we found the patient behind the bar. He declared he was all right. He had slept well, except when compelled to arise to evacuate his bowels, which occurred three times during the night. I saw him some time afterward and he had had no further trouble.

Although many of the symptoms that usually accompany intestinal obstruction were wanting in this case, such as pain, tympanites, etc., still, the sudden constipation and the total ineffectiveness of purgatives of various kinds were good grounds upon which a true intestinal obstruction might be supposed. It must, furthermore, be considered that pain may be absent altogether as well as tympanites, as has been pointed out by Mr. Treves in his Jacksonian prize essay, and not manifest itself until after the obstruction has persisted for some time. This absence of pain is well illustrated by the clinical histories of Cases I. and IV. in my paper on "Treatment of Intestinal Obstruction by the Force Pump," in the number of *The American Journal of the Medical Sciences* for January, 1886; in Case I., where there was clear and undisputable evidence, as there related, of intussusception, there was very little pain and only complained of when questioned about it; and in Case IV., where the patient, a few days before her death, though the trouble was of some standing, had walked around visiting friends, ascending innumerable stairs in her peregrinations. A most striking illustration of this point is furnished by the case reported by Dr. John McGown of a patient suffering from intestinal obstruction for a period of nine months. In his report the doctor says, "He complained of no pain at this nor at any time during the whole course of the disease.[1]

I felt convinced, however, after a careful examination of the patient, that we were not confronted by a true intestinal obstruction. The fact of absence of all manifestations upon the abdomen (though this *per se* does not count for much frequently), that the patient had been well up to the date of the setting in of the constipation, that he jumped out of bed without difficulty and raced around the room (though this latter is not a reliable diagnostic sign as already shown)—in fact, the ensemble of the case led me to believe that we had to deal with some temporary inhibition of intestinal action, and not with an obstruction of the lumen—and that a powerful stimulus to the muscular walls and nervous filaments would bring about the desired effect. To this object the treatment already related was directed and the result verified the diagnosis.

As regards the etiology of the inhibition in this case, it would be no difficult matter to invoke a simple inertia of the intestinal tract, such as is frequently met with; the only obstacle to such an assumption would be the fact that ordinary inertia or constipation is generally easily overcome by the use of a purgative, more or less strong, according to the habit of the patient, whilst in the case here related these remedies seemed ineffective. However, even this might be explained.

There has presented itself to me in this connection, the question, Has the alcoholic habit, or rather the imbibition of a considerable quantity of alcoholic beverage daily, played any *rôle* in this sudden inhibition of intestinal action? It is well known that alcohol imbibed produces an irritation of the peripheral nerves, and, as has been demonstrated, may proceed so far as to produce ataxia and paralytic conditions either by atrophy or destruction of nerve structure,[1] and though it may perhaps be affirmed that beer containing but a minute quantity of alcohol and having considerable diuretic properties which cause its early elimination from the system, cannot bring about such severe irritation as could ultimately result in atrophy or destruction, still it cannot be denied that even this mild alcoholic beverage does produce irritation, or stimulation if it so please, of the peripheral extremities of the nerves. This is well illustrated by the increased appetite felt by persons with weak digestion or overworked persons after taking a glass of beer before meals; the relief of the sensation of "sinking in the epigastrum," so frequently experienced by nervous or debilitated persons, by taking a little ale or beer, and many other phenomena of this character that come under the observation of every practitioner. The deduction might, therefore, be readily made that a continuous consumption of even such mild liquor in considerable quantity could bring about a condition of obtundity of the peripheral nervous filaments; and, as it has been demonstrated experimentally that alcohol has a peculiar affinity for the stomach and bowels,[2] it could be readily explained why such a condition of the nervous filaments should supervene more readily in these organs than in other parts of the body.

If it be objected, however, that the intestinal canal is not under direct control of the nervous system, that the food and other matters passing through it are sufficient to excite peristaltic action,[3] another explanation can be offered. It is well known that alcohol has a relaxing effect on the muscular structure,

and it might, if taken steadily day by day, short of actual intoxication, produce such a torpor of the muscular coats of the intestine that they would not respond to the usual stimulus.

Or there may be produced such a condition of chronic congestion of the parts as to prevent perception of the usual stimulus.

I have observed clinically in extensive beer drinkers that at times a sudden torpor seems to come over the intestinal tract, manifesting itself by constipation and a free development of flatus, so that they will feel bloated (the belly is very tympanitic) and have difficulty in breathing—and certainly extensive tympanites is an evidence of paresis of the bowels.[1]

Case II.—Ch., æt. sixty-three. Rolling mill boss; short of stature and ponderous in weight. Has been sick for some days; cannot pass his urine well; great dyspnœa so that he cannot lie down; cannot retain anything upon his stomach. He has been under medical treatment since the outset, but seeing no improvement he discharged his physician and, on the advice of a friend, sent for me. An examination revealed enormous tympanites of the abdomen. No soreness, but complained of griping pains; he had had no stool for five days. He was afraid, from what his physician said, that his bowels were tangled. I directed that he be given an injection with hot water, temperature about 103°. His wife procured an ordinary syringe and injected about a pint, I remaining to see that the clyster was properly administered. This passed off with a free discharge of flatus; about ten minutes later he was given another injection, about the same quantity as before of spring water at the ordinary temperature (this was in summer); it soon passed off with abundant discharge of flatus and some fecal matter. Fifteen minutes after this another hot-water injection was given and came away with a large stool. He said he felt very much relieved and lay down and rested. The same afternoon he took some beef-tea and retained it. I ordered him some tincture of nux vomica with a little Fowler's solution. The next day he was at work.

Case III.—Mrs. G., æt. fifty-five, woman of short stature, very fat, and large pendulous belly. Complains of great pain in the abdomen. As I have treated her frequently for such attacks, and it being late in the evening I prescribed an opiate, directing the same to be repeated every hour and a half until suffering was relieved. Returned next day and found her no better; still suffering great pain—in fact, had suffered all night; her abdomen was very much distended and painful. Her bowels not having moved (her habit being every third or fourth day), I directed that a large dose of oil be given, to be followed by an opiate after the bowels had acted. On my afternoon visit I found that the oil had not acted. I ordered it repeated with same directions as in the morning. The next morning early I was summoned to her. She complained of greater pain than before; she could not rest all night; she had thrown up the oil and vomited everything after that. She was short of breath and was afraid that she would choke. The tympanites was more marked. I directed that she be given an injection of hot water. This was done and a considerable discharge of gas soon passed away. She felt greatly relieved after this, the griping pains ceasing and the choking sensation disappearing. I directed her daughter to repeat these injections every two hours until she had several stools. Next morning I found her much better; her bowels had moved; the pain had ceased altogether and she had slept well all night; the tympanites was gone; she felt very much prostrated. A rest of another day in bed, good nourishing food, and a little brandy, and she was well and about.

The great resemblance of these two cases to true intestinal obstruction is apparent; we have the symptoms that we find in the most marked cases of this disease. We have the constipation, in the first case of five days' duration, in the second case two days, though if her habit as regards stools had not been known to me, I might have counted it five days also; there were the pain, the distended belly or bell-bombé (upon which some lay great stress), any lastly, in Case II. the urinary difficulty. Neverthed less, I say with certainty that these were not case-of true intestinal obstruction, but that the whole difs ficulty lay in the superabundant flatus to which people with large pendulous bellies are prone, especially elderly people with defective teeth and also persons whose digestive powers have, from some cause or other, become enfeebled; this superabundance of flatus causing a paresis of the intestinal tract and thus inhibiting its action. Furthermore, the success of the treatment, a small enema, but of powerfully stimulating character, so as to provoke powerful contraction of the bowel and thereby the expulsion of the flatus, proves the correctness of the diagnosis.

That it is possible to mistake cases of this character for true intestinal obstruction is very evident, and it is not stretching the imagination to assume that many of the cases reported as intestinal obstruction cured by puncture with a fine trocar, and in which the main feature of the operation was the evacuation of a large quantity of flatus as is expressly stated by Mr. Worthington in the report of his case,[1] were cases of inhibition of intestinal action from overdistention of the bowels by flatus. Mr. Treves, in his book on *Intestinal Obstruction*, chapter on treatment, section puncture with fine trocar, quoting two cases, expresses great doubt as to their being true intestinal obstruction, for his own experience with this method has not been such as to lead him to believe in its efficacy. This opinion is corroborated by the history of the case of Dr. McGown, in which, although the patient was temporarily relieved by this procedure, it required other measures to effect a cure.[2] It has, perhaps, been the habit up to the present time of calling all cases intestinal obstruction where the main feature is an inhibition of intestinal action without regard to the etiology of the inhibition; but at the

[1] Quain's Dictionary of Medicine. Article, "Tympanites."

[1] Case of Intestinal Obstruction Relieved by Puncture of the Bowels, by James C. Worthington. British Medical Journal, 1882, vol. ii.

[2] Although the title of his article would seem to indicate that the patient was cured by the colopuncture, a careful reading will demonstrate that the colopuncture only relieved, and that it was the other procedure that cured.

present day when operative interference by laparotomy is growing more in favor, and resort to it advocated at an early stage of the case, the question of differential diagnosis between pseudo- and true intestinal obstruction certainly becomes one of great importance. This is well shown by the case mentioned by Dr. Lusseau of the hysterical form of pseudo-strangulation: "In this instance the resemblance was so exact that *an operation for the relief of the intestinal obstruction was proposed.* The patient, however, soon recovered when treated by antispasmodics."[1] It is important to know whether a given case may be one in which the question of operation may present itself for consideration at any moment, or whether it be one of those pseudo forms that end in recovery with very little treatment. Such a distinction is furthermore of importance for the statistics of intestinal obstruction, that a correct estimate may be had of the number of cases, number of recoveries, as to the most successful means of treatment, etc.

I do not think it necessary to give any detailed explanation for the alternation of the hot and cooler injections as detailed in this paper, and mentioned in my paper, "The Treatment of Intestinal Obstruction by the Force Pump" (Ibid.); by this alternation the bowel is not habituated to the enema, and each clyster has a stimulating effect both on the muscular coats and on the peripheral nerve fibres, and excites peristalsis.

I will only add, in conclusion, that I believe that when enemata are resorted to for the purpose here indicated or for true intestinal obstruction, they should be of hot water; or if the patient prefer, and there are no contraindications, of cold water, that an effect may be immediately produced: the injection of lukewarm water is without effect, as can be readily seen by a study of many reported cases.

THE INTESTINAL SUTURE OF APPOLITO.

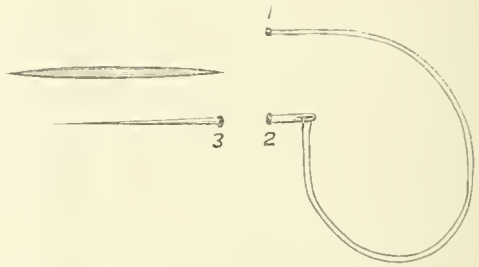
By ROBERT P. HARRIS, A.M., M.D.,
of Philadelphia.

Through the kindness of Dr. Domenico Peruzzi, a colleague of Prof. Pietro Loreta of Bologna, I am enabled to present a description of the suture which the latter has used so successfully in his divulsive operations upon the cardiac and pyloric orifices of the stomach, for closing the incision made in this viscus, so as to secure it against the escape of fluid nutriment, and establish an early union of the wound.

Since the time (1824) when the celebrated Jobert (de Lamballe) established the fact that intestinal wounds could be most rapidly united by securing their peritoneal surfaces in contact, by a process of welting, throwing up a ridge on the inner surface of the bowel, a revolution has been gradually effected in the manner of treating intestinal injuries whether accidental, or done by the knife of the surgeon in the exsection of morbid parts. Althongh the suture of Jobert was a very objectionable one, the principle on which it was founded soon led to improvements, and two years later (1826) to the design of the interrupted stitch of Lembert, made of such renewed importance of late in its application to securing the peritoneal portion of the uterine wound in the Cæsarean method of Sänger. The value of this application was shown in an operation performed in Philadelphia in November, 1884, by Dr. Thomas M. Drysdale, in which the uterine wound was so effectually secured that its peritoneal portion was found fully united after a survival of twenty-six hours, and no fluid had escaped into the peritoneal cavity. The old glover suture of the intestine, not being adapted to the new principle of closure, was modified and became the spiral uninterrupted suture, in which the stitches are taken as pins are inserted in a pin-paper, and the ridges are drawn together as in the manner of the Lembert suture. In 1844, Dr. Gély, of Nantes, devised the double parallel uninterrupted suture made with two needles and one thread, the thread ends being crossed to opposite sides of the wound after each stitch was taken, and the whole drawn and secured at the terminus by a single knot.

The suture of Appolito is a simplification of that of Gély, and is much more easily applied, as it is inserted with one needle which carries a double thread. When the needle is threaded, a knot is tied over a little ball of aseptic cotton, a modification of the plan of Reybard, and the needle is passed from within outward beyond the end of the wound, leaving the ball on the inside, as in Fig. 1: and the first

Fig. 1.



longitudinal stitch is taken parallel with the line of the wound on the opposite side, as is also shown. In Loreta's operation, the initial puncture is made about a centimetre beyond the end of the wound, and at the same distance from the line of it at the side: the stitch-holes will be two centimetres distant across the wound, and each internal stitch will be taken parallel to the wound on alternate sides, a centimetre long and a centimetre from the edge of the wound, as in Figs. 2 and 3.

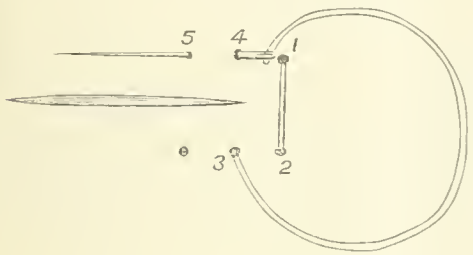
When the last stitch is taken, the thread is cut on one side and a Lembert suture is inserted with the remaining strand on the opposite side, as shown in Fig. 3. The double thread is drawn successively from puncture 3 to puncture 11, and the single strands at punctures 11 and 12 are drawn, tied securely and cut near the knot. The line of direction of the wound will now be seen to present a sinuous fissure, and not a straight one as after the closure of Gély, provided the stitches of the latter

[1] Intestinal Obstruction, by F. Treves, p. 405. Italics mine.

have been taken in pairs of exactly the same length, otherwise there will be a tendency to gape.

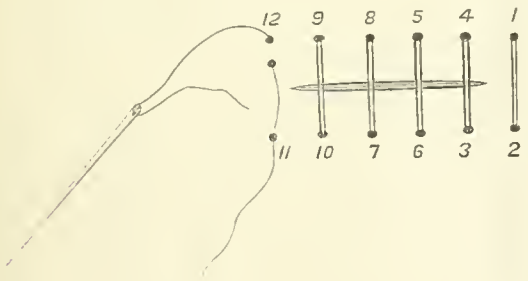
The Appolito is no doubt a better suture for the stomach than it would be for the intestine, where the walls are thinner and more yielding. In a woven fabric, the single stitch of Appolito would be known as a *running stitch*, and that of Gély as a *double stitch*, the latter, upon mechanical principles, being con-

Fig. 2.



sidered the more secure, although the former in handwork is more employed for its simplicity, where strength is not of absolute necessity. To make a single stitch that will not draw, would be more complex than either. The Lembert suture is valuable for small or cross wounds of the bowel, but must be inserted at very short intervals to prevent gaping. The value of any particular form of suture does not depend so much upon its design, as upon the mechanical capability of the operator in accurately carrying it out. How rarely do we see, even in a skin-wound, all of the needle punctures made at exactly opposite points, as shown when the threads come to be tied across it. Accuracy is all-important

Fig. 3.



in making the closure of an intestinal wound effective, whether it be made by the suture of Lembert, Gély, or Appolito: it is more easy, by either, to pucker the wound, than to avoid doing so. In all intestinal sutures, as the thread ultimately escapes by ulceration into the bowel, it is the practice to carry the stitches through all the coats, and not partially, as was once the custom. The material preferred is pure Chinese silk which has been boiled in water to separate the gummy matter.

MEDICAL PROGRESS.

Therapeutics of Cholera. — Dr. Grant-Bey thus describes his method of routine treatment in cholera epidemics.

On July 14, when the malady was raging at Geezeh, at our very doors, by the request of the local board I drew up elaborate instructions about cholera, and indicated the remedies that should be used, viz.:

1. "A mixture," of which the following is the composition and the instructions for use:

R.—Tincturæ opii	. . .	℥ ss
Spiritus camphoræ	. . .	℥ ss
Tincturæ capsici	. . .	℥ ss
Chloroformi	. . .	℥ iss
Spiritus vini rectificati	.	ad. ℥ iiss.—M.

Sig.—For the premonitory diarrhœa of cholera, twenty drops for an adult, and five drops for a child, in half a wineglass of water or chamomile tea, every hour or every two hours, etc., till diarrhœa ceases; but if vomiting or cramps set in, then leave off the mixture and give the "Anticholérique Pasteur," of which the following is the composition and mode of administration:

R.—Hydrargyri bichloridi	. .	gr. ij
Spiritus chloroformi	. .	℥ x
Spiritus camphoræ	. . .	℥ v
Tincturæ lavandulæ co.	.	℥ ss
Spiritus rectificati	. .	ad. ℥ ij.—M.

Sig.—To be used when diarrhœa cannot be checked, and vomiting or cramps commence; a teaspoonful (℥ j) to an adult, and thirty drops to a child, in chamomile tea, every quarter of an hour, every half hour, every hour, etc., according to urgency of symptoms.

On July 15, the epidemic reached Cairo, and its suburb Boulaq was devastated by it. Out of 1800 men employed at the Boulaq railway workshops, fifty-nine died of cholera. Many others who were attacked recovered after the prompt use of the remedies, and most of those who died did not take the medicine.—*Albany Medical Annals*, August, 1886.

Persistent Sweating in Intermittent Stages.—In *The Asclepiad* for 1885, vol. ii. pp. 190–192, there is related from the *Medical Press* the history of a case by Dr. Myrtle, of Harrogate, in which the patient, a man seventy-two years old, died from persistent sweating. Since then I have received the details of other cases, similar but not so severe, to one of which attention should be called.

In this instance the patient, Miss C. E. de M., has herself supplied me with the history of the symptoms and with a memorandum and temperature chart by Dr. Dabbs, of Shanklin, Isle of Wight, under whose care she remained during the whole of the attack. Miss M. had suffered, three years previous to the occurrence of the particular symptoms now under consideration, from typhoid fever, and also from some signs of a tuberculous nature, so that she was an invalid before the attack. She took what she considered to be a chill in the summer of 1884, and suddenly began to perspire. The perspiration came on every day from ten to

one o'clock, and again from ten to one o'clock in the night, with occasional repetition in the early part of the evening. During these times she was simply bathed in perspiration, so that all her clothing was completely saturated, the bedclothes sharing the same saturation when she was in bed during the paroxysm. In order to give every attention to the various remedial measures that were suggested, a professed nurse was obtained from London, and all changes of treatment, general and local, were tried, but, as in Dr. Myrtle's case, without any effect. The perspirations began on August 1, 1884, and continued until the first days of November, when they suddenly and completely ceased. Owing to the existence of continued pain in the epigastrium, Dr. Dabbs inserted a seton over the seat of pain, and it is worthy of note that the cessation of the perspirations occurred at the time when the discharge began to take place from the seton. This practical fact deserves remembrance in similar intractable forms of the disease. Miss M. has had no recurrence of the intermittent perspirations since 1884.—Dr. B. W. Richardson, in *The Asclepiad* for July, 1886.

The Jugulation of Typhoid Fever by Sulphate of Quinia and Lukewarm Baths.—At the session of the Academie de Médecine of August 3, M. Péchollier, of Montpellier, read an essay thus entitled. He concluded that, by its antizymotic action, quinine, when associated with lukewarm baths, shortens the course of typhoid fever to a mean of from fourteen to sixteen days. He bases his statements upon over sixty-five consecutive cases, speedily cured, without any failure. —*L'Union Médicale*, August 5, 1886.

Beautifying the Skin.—In the work on diseases of the skin edited by Professor von Ziemssen, Dr. Heinrich Auspitz, of Vienna, makes the following observations upon this supject:

1. A healthy integument is not necessarily beautiful. Even if all requirements concerning diet, residence, atmospheric and climatic conditions, etc., are carried out, the complexion is often extremely bad. The general condition of health has no influence upon the beauty of the complexion, though it has upon the health of the skin.

2. Cleanliness is a *sine qua non* of the beauty of the complexion, though it does not play a great part in the health of the skin.

3. Water is serviceable to the skin in only moderate amounts and at moderate temperature. Very cold or warm baths, when used to excess, diminish the elasticity of the skin and its power of resistance to external irritants.

4. Distilled and so-called soft water are more suitable for washing, and less irritating than hard water.

5. The hard soda soaps are usually preferable to the soft potash soaps for toilet purposes. The quality of soaps depends upon the quality of their constituents and the thoroughness of their saponification. Good soaps must not contain free alkali, or any foreign irritating substance. The addition of moderate quantities of perfumes does not materially change the quality.

6. Simple, finely ground powders, such as starch, magnesia, etc., are entirely innocuous, and often act as a useful protection against external irritants.

7. Frequent application of alcohol abstracts the water of the skin, makes it dry and brittle, and impairs its nutrition. This is also true of glycerine. All toilet washes containing alcohol to any considerable extent should be avoided.

8. This is true to a still greater extent of other additions to washes, such as corrosive sublimate, mineral acids, certain metallic salts, etc.

9. Camphor acts merely as a bleaching powder. This is also true of benzoic resin, sulphur flowers, and substances containing tannic acid.

10. The use of sweet-smelling oils and fats should be employed to a greater extent than is now done for toilet purposes.

11. This is particularly true with regard to the growth of the hair. The nutrition of the scalp should be increased by the rational application of fat (for example in the form of oil baths by means of the application at night of a sponge soaked in oil upon the scalp), and the greater use of simple pomades. These should be applied to the roots of the hair rather than the shafts.

12. Substances should be avoided, or sparingly used, which abstract water from the skin and the roots of the hair.—*Southern California Practitioner*, August, 1886.

Stomach Operations, Performed at Prof. Billroth's Klinik from 1880 to 1885.—Briefly, the cases and operations are as follows: Gastrotomy, one case. This was done on a patient, æt. nineteen, for the extraction of some teeth. The patient recovered in five weeks. Gastrorrhaphy, two cases; both died. In one, the operation was performed for rupture of the stomach after a plentiful meal. Death occurred from collapse in four hours. In the other, from a gunshot wound in a woman aged sixty-three. Death from peritonitis and collapse in twenty-eight hours. Gastrostomy, four cases. In one, for œsophageal stricture, the result of swallowing a caustic alkali. Death occurred on the ninth day from inanition. In a second, for carcinomatous stricture at the cardiac orifice. Death, one month and a half after the operation, from croupous pneumonia. In a third, for the same reason as the second. Death, twenty-four hours after from inanition. In a fourth, also for carcinomatous disease of cardiac orifice. Death, eighteen days after from inanition. Gastrectomy, eighteen cases, of which eight recovered, and ten died. These cases consisted of fourteen pyrolectomies for carcinoma of the pylorus, six of which recovered. One pylorectomy, combined with gastro-enterostomy, also for carcinoma of the pylorus, death in four months from return of the disease; three pylorectomies for cicatricial stenosis, one recovered; and one, partial resection of the pylorus (removal of a wedge-shaped piece), with death.—*Glasgow Medical Journal*, August, 1886.

Action of Urine on the Peritoneal Cavity.—At a recent meeting of the Russian Medical Society Dr. D. O. Oll recorded the results of a series of experiments on eleven dogs, in each of which a ureter was incised in such wise that its contents should drain into the peritoneum. The permeability of the ureter was assured by the introduction of a small glass tube in its upper end. Wound dressed with Listerian precautions. Eight dogs died of peritonitis between the third and sixth day after operation. The three survivors were

sacrificed on the seventeenth, twenty-fourth, and twenty-fifth day respectively. In them the urine had produced simply a local peritonitis with adhesions, resulting in obliteration of the artificial fistula. Not a drop of urine was found in the abdomen. There was dilatation of the wounded ureter and of the pelvis of the kidney, degeneration of the renal parenchyma. The author concludes that fresh urine is absorbed from the peritoneum without any bad results provided antiseptic precautions be used.—*Nouvelles Archives d'Obstétrique et de Gynécologie*, No. 5, 1886.

Differential Toxicological Behavior of Gelsemine and Strychnine.—The possibility of mistaking a case of strychnine poisoning with criminal intent for an accidental intoxication caused by a prescribed preparation of gelsemium recommended to our notice Raimondi's pertinent comparative investigations as set forth in the *Ann. di Chim. Med.*, Sett., 1885. If it is possible to recover enough of the poison to enable us to experiment with it on warm-blooded animals, the nature of the poison is readily established. If, however, the scantiness of the substance in question allows only experiments on frogs, the following differential features must be our guide:

1. In gelsemium poisoning the motor paralysis has a central cause, which does not apply to strychnine.

2. The effects of strychnine manifest themselves with equal intensity over the whole body, while in gelsemium poisoning the posterior extremities show the clonic-tonic convulsions more distinctly than the anterior ones.

3. Immediately or shortly after one strychnine paroxysm, a second may follow; in gelsemium poisoning considerable time usually elapses between the single paroxysms.

4. The stage of tetanus from strychnine may last several days, that of gelsemium rarely exceeds an hour.

5. In chemical respects the two drugs present also some characteristic differences, which, under the name of Schwarz's differential reactions, are detailed in Raimondi's paper.—*Therapeutic Gazette*, Aug. 16, 1886.

An Antiseptic Dentifrice.—Dr. A. D. MacGregor, of Kirkcaldy, writes in the *Brit. Med. Journal* of July 10, 1886, as follows: "Few medical men, I suppose, have ever given a prescription for tooth-powder (such a matter is beneath their notice), and the selection of the ingredients for the various powders and pastes in vogue for the purpose of beautifying and cleansing the teeth is left entirely in the hands of those who certainly should not know better than medical men. I have frequently trespassed on this debatable ground, and recommended a particular dentifrice. In view of the extremely important part the teeth play in the economy of life, I never hesitate occasionally to inquire as to the attention they receive. A tooth-powder should possess certain characteristics: it should be antiseptic, cooling, agreeable to taste and smell, and have no injurious action on the teeth. After use, it should leave the teeth white, and a sensation of freshness and cleanliness in the mouth. As an antiseptic in this connection, nothing can displace boric acid. For years I have used the following powder, and can recommend it: Boric acid, finely powdered, 40 grs.; chlorate of potassium, 30 grs.; powdered guaiacum, 20 grs.; prepared chalk, 60 grs.; powdered carbonate of magnesium, to ℥j; otto of roses, half a drop. The boric acid in solution gets between the teeth and the edges of the gums, and there it discharges its antiseptic functions, the chlorate and guaiacum contribute their quota to the benefit of the gums and mucous membranes generally; the chalk is the insoluble powder to detach the particles of tartar which may be present, and the magnesia the more soluble soft powder which cannot harm the softest enamel."

Actinic Contrast in Photo-micrography.—Dr. George A. Piersol writes as follows in the *American Monthly Microscopical Journal*, for July, 1886:

In many cases it is expedient to prepare objects especially for photography. For such cases a very valuable adjunct will be found in the use of different colored lights produced by tinted glasses, carefully adapted to the intensity and color of the staining. The use of glass, or of solutions of a color complementary to that of the object, has been long employed in the arts in reproducing paintings. Koch, in his *Traumatic Infective Diseases*, relates his experiences with this method, but condemns it as impracticable. On account of the length of exposure and vibration "the picture does not have sharpness of outline sufficient to enable it to be of use as a substitute for a drawing, or, indeed, even as evidence of what one sees."[1]

Notwithstanding the unfavorable experience of this skilful investigator some subsequent results by this method have been most encouraging. Defrenne obtained excellent photographs of the *Bacillus tuberculosis* by means of fuchsin staining and green glass, and quite recently my own experience with this same bacterium and stain has been very gratifying. Since then a number of modifications have been tried. As a result of these experiments, the practical deductions have been reached that when the staining and thickness of the specimen are insufficient to give the necessary actinic contrast with the color of the field, we can best succeed by employing a colored glass, the tint of which will be such as to give the contrast as well as to afford light sufficiently to impress the plate where not occupied by the object. Such a color will not be the complementary one in many instances. With blue stainings the use of the complementary yellow would yield but a faint image, since the weak actinic power of the transmitted rays are insufficient to affect deeply the unoccupied parts of the field. The substitution, however, of a suitable shade of green affords sufficient contrast of the object as well as permits the passage of rays of sufficient actinic power to impress adequately the surrounding parts of the plate.

With all these colors the exposure is greatly lengthened; with a medium green it being five to seven times longer than with blue light; as, however, the normal exposure is seldom over one second, the increase has practically little disadvantage. Not only for very minute objects, as bacteria, stained with methyl-blue, under high power, but equally for very thin hæmatoxylin or carmine sections under low amplification has this green glass proved most useful. By its use it is always possible to obtain pictures, where all the merits of vigorous negatives with the beautifully sharp details alone

[1] Magnin-Sternberg. *Bacteria*; 2d ed., page 195.

obtainable from the thinnest sections are combined, and where the usual methods yield but a weak image.

These suggestions apply especially to sunlight. To those engaged in such work, who have never employed these means, the shades of green offer themselves as valuable modifications of illumination well worthy of a trial. The exact tint required—a matter of importance—must be determined for existing conditions by each manipulator.

Resolvent Solution.—Descroizilles commends as a resolvent solution for local use in strumous enlargements in children the following mixture:

Sodium chloride	40 parts
Magnesium sulphate	15 "
Tincture of iodine	1 part
Distilled water	150 parts

Compresses are saturated with this solution and applied as needed.—*L'Union Médicale*, August 3, 1886.

Final Results of Operation for Cancer of the Lip.—Interesting statistics concerning the therapeutic results of the surgery of this affection, are collected from the clinic of Bruns, Tübingen, by A. Woerner. An abstract in the *Centralblatt f. Chirurgie* states that of 305 cases operated upon at Tübingen, the affection occurred in females as compared to male patients in the relation of one to nine. The average age was 62 years. In 236 cases no mention is made as to the tobacco-smoking habits of the patients. Fifty-one were inveterate pipe-smokers. In eleven cases a trauma was the first origin; in seven cases neglected warts became the seat of the first start. In sixteen cases the upper lip was affected. Of the 305 cases 217 were operated upon by 354 different operations. Simple excision and union seemed sufficient in 224 cases; in 28 resection of the maxilla was necessary to total removal. An interesting statement is that one male patient, whose case was inoperable, and who was treated by electrolysis, developed a violent erysipelas. With the subsidence of this, the tumor had almost vanished. The man had no return and died one and a half years after from other causes. Of the 277 operated patients, recurrence of the malignant growth ensued in 111 persons; 87.2 per cent. recurred inside of a year, 128 after a year. Of the 160 cases that showed no return, 71, or 25.6 per cent., died from other causes, after an average duration of life after the operation of 8.4 years. The 89 that still lived averaged 5.8 years since the operation. Of the whole number, 160 cases, 106 lived over three years; hence the latter number certainly may be considered as permanently cured. Woerner also compares the previous reports on this subject made by Thiersch, v. Bergmann, Billroth, Kocher, etc. The sum of these observations is 866 cases. These patients show results very close to the figures of Woerner. Of the whole number of returns, 87.6 occurred within the first year. The percentage of those that survived three years without a return was 28.1 per cent., as compared with 38.2 per cent. at Bruns's clinic.

Treatment of Epilepsy.—Wildermuth, in the course of a long career at the head of an institution devoted to epileptics, has had occasion to make trial of all remedies of reputed value in epilepsy, and has finally concluded that the treatment by bromides is indicated in the majority of cases.

In combating epilepsy, or, more properly speaking, the epileptic state, Wildermuth exhibits the bromide of potassium in the initial dose of thirty grains in children, and seventy-five grains in adults. The dose is gradually augmented to one hundred and twenty grains, and, very rarely, to one hundred and fifty grains.

The bromide is given in water or milk, and its exhibition is followed by physical exercise in order to decrease the likelihood of resultant gastralgia.

Iodides and chlorides are badly borne.

When medication is suspended, it is advised that the doses be gradually and slowly decreased.

The treatment may produce disagreeable consequences, which should be met more than half-way. The dental and gingival alterations are prevented by gargles of potassium permanganate, and cutaneous eruptions by the daily administration of Fowler's solution, lukewarm baths, and inunctions of Hebra's ointment. With this ointment, also, the eruptions of bromism are treated when they appear, and when they are very rebellious he does not hesitate to use the sharp curette.

The circulatory troubles incident to the bromine treatment necessitate cessation of the medicament, administration of coffee, shower-baths to the spine, and massage of the limbs.

When patients are very susceptible to the pure bromide of potassium, the daily ingestion of a wine-bottle or less of Erlenmayer's "bromized water" is to be preferred. The formula of this is as follows:

Potassium bromide,	
Sodium bromide	āā gr. lx.
Ammonium bromide	gr. xxx.
Liquor ammonia	gt. j.
Carbonated water	ʒxx.

In recent cases and in adolescents Wildermuth employs a somewhat smaller dose of the bromides, and adds one-tenth to one-thirty-third of a grain of atropine sulphate. In desperate cases he has used the osmate of potassium, in doses of from one-seventieth of a grain to one-fourth of a grain, together with zinc oxide, according to the method of Herp.

He has seen no benefit from the use of curare or absinthe. The continuous current is chiefly of advantage in combating choreiform manifestations; the anode applied to the sternum, and the cathode to the spine. In subduing the psychical excitement, hydrotherapeutic methods have proven most useful; especially the moist pack and massage, gave favorable results in cases in which somnolence was very pronounced.

The dietetic regimen consists in the moderate use of meats, avoidance of spices, sobriety, and abstinence from tea and coffee.

The treatment of the access appears useless when the crises succeed each other rapidly. If they are more rare, he tries the wet pack, ice to the head, and a double or triple dose of bromide. Chloroform is discarded as unsafe, and chloral is reserved to combat the excitement in the intervals of the access. In cases where arrest of the heart is threatened, he commends the subcutaneous injection, in the thoracic region, of camphorated oil, up to the maximum dose of two fluidounces.—*Gazette Hebdomadaire de Médecine et de Chirurgie*, August 6, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, AUGUST 28, 1886.

ECLAMPSIA.

THE most notable contributions which have recently appeared on this important subject are the chapter on puerperal nephritis in DR. PURDY'S excellent book on Bright's disease, and a lecture by LEYDEN, "Ueber Hydrops und Albuminurie der Schwangeren," published in the *Zeitschrift für klinische Medicin*, Bd. II., Heft 1, 1886.

An examination of these papers justifies the following conclusions:

1st. That the majority of cases of puerperal eclampsia are accompanied by albuminuria or dropsy, or both, but a certain number are unaccompanied by either.

2d. That the majority of cases are associated with and are the direct result of kidney disease.

Thus, out of 135 cases of eclampsia collected by Brummerstaedt, of which 51 were fatal, there was albuminuria in 106, or less than 80 per cent.; in 29, or more than 20 per cent., it was absent. Again, according to Schröder (*Text-Book of Midwifery*, edition of 1884), from 3 to 5 per cent. of pregnant women have albuminuria; but of women in labor a much larger proportion have it—according to Flaischlen 17 per cent., to Würst 20 per cent., and to Mörike 37 per cent.; the proportion of albumen varying greatly and being often very small. According to Rosenstein out of every 8 cases of albuminuria in pregnancy 1 has eclampsia, and according to Schröder 1 woman out of every 500 confined has convulsions. It is evidently impossible to draw any further conclusions from these statistics than that, while not every case of albuminuria in pregnancy is going to be a case of convulsions, the presence of albuminuria makes it more likely that there will be convulsions, a fact which is of great practical importance.

How is it with dropsy? Leyden very correctly says we know less of the relation between the albuminuria and the dropsy of pregnancy, although it is certain that the two do not stand in a necessary corresponding relation; and it is true, also, that anasarca is much more frequent in pregnancy than albuminuria, there being a not inconsiderable number of cases of œdema gravidarum without albuminuria, while it is equally true that albuminuria may occur without dropsy. Leyden is inclined to believe that where albuminuria and dropsy are both present, as a rule the dropsy precedes and the albuminuria follows, while Frerichs regards the albuminuria as preceding, in our opinion, rightfully, where the two conditions depend upon renal disease.

And this brings us to the second and most important of our conclusions—the relation of eclampsia to kidney disease. Both albuminuria and dropsy betoken some obstruction to the circulation in the kidney, and very early it was suspected that the kidneys were at fault. Such suspicion was soon justified by the results of autopsies, first by Rayer but subsequently by many others. The precise relation of the two conditions and the proportion of cases of albuminuria or dropsy, or both, in pregnancy, to alterations in the kidney, is still unsettled in the minds of many.

With a view of getting at this a little more precisely, let us return for a moment to the question of the relation of albuminuria and dropsy to renal disease. It has been said that both point to a derangement of circulation in the kidney, but this is not true of both in equal degree. We may say of albuminuria that in all cases except where it is due to pus from some part of the genito-urinary mucous surface, it is the result of such deranged circulation. But not so with dropsy. It is well known that we may have dropsy from obstruction to the circulation elsewhere than in the kidney, and such obstruction may occur in pregnancy, indeed it is much more prone to occur in pregnancy than in the non-pregnant state, by reason of the pressure exerted by the gravid uterus. This is a very different thing from saying that the renal changes are the result of the pressure exerted by the gravid uterus, which we do not at all believe. As the result of our belief, however, we regard dropsy without albuminuria in pregnancy as a much less serious symptom than either albuminuria alone or dropsy with albuminuria. Indeed, we may go farther and say that, where there is dropsy in pregnancy without albuminuria, we may conclude that the kidneys are not seriously involved, and that the danger of eclampsia is less, so well assured do we feel that, where there is renal disease in connection with pregnancy, the albuminuria must be pres-

ent either alone or in connection with dropsy. It is true that Bright's disease may occur in the non-pregnant state accompanied by very small albuminuria, or even without albuminuria. But in these forms of kidney disease the process is a very slow one as compared with Bright's disease the result of pregnancy, besides being, as a rule, of a different nature—being interstitial from the beginning; although some observations of Leyden, presently to be referred to, go to show that cirrhosis of the kidney may also result from pregnancy.

Reiterating that by far the largest proportion of cases of eclampsia are the result of renal disease, are we able to foretell the precise alterations—in other words, the form of Bright's disease—present? The most recent studies seem to necessitate some change of view as to the form of kidney disease present. Dr. Purdy gets over it very nicely by calling the disease puerperal nephritis, and his account of the morbid anatomy is very brief. For the purpose of treatment perhaps it is not necessary to be more precise. But the demands of modern medicine require us to be as precise as possible. Both Rosenstein and Bartels regard the disease as an acute parenchymatous nephritis. Undoubtedly many cases of puerperal nephritis are recognized in the stage of acute parenchymatous nephritis. In such there is blood in the urine, and blood casts, and much albumen. But at the stage at which death occurs and autopsies are obtained, it is more frequently the second stage of the disease which is found. Dr. Purdy correctly says: "Hemorrhagic extravasations are less frequent and pronounced than in other forms of acute nephritis, especially the scarlatinal form; yet patches of migrated blood corpuscles may sometimes be seen between the convoluted tubules and about the glomeruli. Epithelial cells lining the convoluted tubules are seen to be swollen, and in some places they have become fatty." Three out of four of Leyden's autopsies discovered fatty degeneration of the cells lining the tubes of the cortex—in a word, the second stage of chronic parenchymatous nephritis. The bloodvessels and interstitial tissue were intact. Leyden reports two cases with a view to showing that the Bright's disease of pregnancy may also be represented by the granular kidney. One case is based on the clinical history, which certainly coincides with that of granular kidney in general, the other is confirmed by autopsy. The pregnancy was normal, except that there was much sick stomach, until eight days before confinement, when swelling of the feet and legs with scanty urine was noted. The labor was natural. Eight days afterward, on rising, the patient noticed her feet swollen, but two weeks later the swelling had disappeared. Then followed a period of apparent health, except that the patient was weak. Then followed morning sickness, headache, weakness, retinitis albuminurica, and the diagnosis of contracted kidney by the oculist consulted. Convulsions finally set in, and the next day the patient died, seven months after confinement. Might not both of these have been cases of previously existing granular kidney, or of the disease developed from its usual causes?

A most important question naturally succeeds the discussion of our second conclusion: Is eclampsia always associated with or dependent on kidney disease? In determining the correct answer to this question, there are many sources of error. In the first place, all negative observations prior to the careful use of the microscope, which has characterized the practice of the last twenty years, must be disregarded, as well as all negative observations of a later date based on other than microscopic examination of the kidneys. We fear this must be the fate of the 106 cases of eclampsia collected by Ingerslev, cited by Schröder, in none of which was there albumen, while at the autopsies the kidneys were found entirely normal. Cautiously, too, should be regarded a case cited by Leyden, as reported by Schulz in an inaugural thesis in 1867, in which the kidneys were found anatomically intact. But Leyden himself, in the paper referred to, says that, in a single case of fatal eclampsia from which the kidneys were sent to him for examination, he found nothing abnormal; and says also "the fact that eclampsia may go on to a fatal issue without the kidneys presenting any anatomically demonstrable alterations, is equally as true as that eclampsia may occur without albuminuria."

With such statements from such authorities we dare not, perhaps, deny the possibility of the occurrence of fatal eclampsia without accompanying Bright's disease, but we feel justified in asserting, emphatically, that such cases must not only be exceedingly rare, but even impossible where albuminuria is present, and, further, that to base any therapeutics on the supposition that such is the case, is almost criminal.

Such rare cases may be of the following kind. In the first place, there can be no doubt that we sometimes meet cases of puerperal convulsions without albuminuria or renal involvement which are analogous to the convulsions of teething or gastric irritation in childhood. They occur most frequently in primiparæ, and often in prolonged labors, where the uterine tissues have been teased to such an extent by the pressure which has been exerted upon them, that the nerve centres with which they are in connection become excitable and explode in convulsions. It is not unlikely, too, that the nerve-centres of pregnant women are like those of children, physiologically more excitable than in the normal state. Such

cases are apt to have only one or, at most, two convulsions. It is not impossible, also, that occasionally one of these may terminate fatally, just as reflex convulsions from other causes terminate fatally. But, certainly, such terminations are exceedingly rare in this class of cases. Further, the whole category is so small that, in treatment, their special causes may be ignored, and the cases treated by bleeding and anæsthesia as though they were uræmic.

On the importance of the diagnosis by a study of the urine of an existing Bright's disease in a pregnant woman before labor sets in, it would hardly seem necessary to say anything at the present day, but for the fact that women continue to be sacrificed to neglect of such examinations, who might have been saved by a treatment directed to the complication.

FARADIZATION IN EXTRAUTERINE PREGNANCY.

The questions raised by the letter of Mr. Tait in our issue of August 14th, give indication of exciting no little controversy; and we cannot refrain from thinking that he is a bold man to challenge so many obstetricians in this country, and so many in Europe, some of whom are acknowledged to be among the most distinguished and able in the profession. These gentlemen have asserted that they have made the diagnosis of extrauterine pregnancy prior to rupture of the gestation cyst, and have destroyed the life of the embryo or fœtus, thereby arresting the pregnancy. Now it is true that in the great majority of cases the anatomico-pathologic proof is wanting, for, by electricity in this country, and by the evacuation of the cyst or by the injection of morphia in Europe, the pregnancy is arrested without detriment to the mother, and so there is no opportunity for an autopsy to verify the diagnosis. But there are five recorded cases of the diagnosis of extrauterine pregnancy during the life of the embryo or fœtus which give conclusive proofs that Mr. Tait is mistaken in his view, for these cases were unquestionably correctly diagnosticated at a period when, according to his statement, a diagnosis is impossible. In 1874, Tarnier diagnosticated a case of extrauterine pregnancy which had advanced to between five and six months; he destroyed the life of the fœtus by morphia, and the condition of the patient subsequently requiring laparotomy, the diagnosis was confirmed. Gaillard Thomas and the late Albert H. Smith have each done elytrotomy in cases diagnosticated as extrauterine pregnancy, and the correctness of their opinion verified. Veit (*Zeitschr. für Geb. und Gyn.*, 1884 and 1885) has twice done laparotomy in cases of tubal gestation about the third month; both women recovered. Here are five very strong and stubborn facts, and until they are disproved Mr. Tait's assertion falls to the ground.

There is another of his statements which is at variance with demonstrated facts according to most authorities, to wit, that all extrauterine pregnancies are tubal. But the discussion occupies a large enough field for the present while limited to the first assertion.

TAKING THE TEMPERATURE IN CHILDREN.

A very ingenious and simple method has been proposed by Filatoff, in the *Archiv für Kinderheilkunde*, vol. vii. part 3, for expediting the troublesome process of obtaining the temperature in children.

He recommends that by the use of a previously warmed thermometer the fall, and not, as is usual, the rise of the mercury be observed. In from one to two minutes the column is found to stop at a point which very closely approximates to the actual temperature of the patient. It is found that the higher the fever, the smaller is the error. Thus, at temperatures of from 103.1° to 104° F., the error does not exceed 0.2° F., while for lower temperatures it may reach 0.5° F. It is, of course, evident that a certain amount of care and skill is requisite in order that the precursory warming of the thermometer be neither insufficient nor excessive.

REVIEWS.

Transactions of the American Gynecological Society for the Year 1885. Vol. 10. 8vo. pp. 357. New York: D. Appleton & Co., 1886.

The Society met in Washington, D. C., on September 22, 23, and 24, 1885, twenty-four out of the fifty-four active Fellows being present. Papers were presented by twelve Fellows, and by three candidates for election; we have only space enough to glance at a few of these. The President's annual address was entitled "Two Rare Cases in Abdominal Surgery." In this Prof. William T. Howard, of Baltimore, takes up particularly the difficulties in the differential diagnosis of morbid growths in the abdomen. The paper elicited an active discussion, Fellows of large experience admitting the great difficulties and uncertainties of abdominal diagnosis.

Dr. Henry J. Garrigues, of New York, presented an important paper upon "Puerperal Diphtheria," with a record of twenty-seven cases, only five of which terminated fatally. Dr. Garrigues has introduced several valuable prophylactic measures in the management of puerperal women in hospitals, of which his antiseptic pad is regarded as having greatly lessened their mortality, preventing the entrance of germs into the vulva and keeping the wards in a cleanly state.

Prof. Joseph Taber Johnson, of Washington, D. C., introduced the subject of oöphrectomy for reflex disturbances of the nervous system, by reporting four cases, three of which ended in entire cure and one died. As sixteen pages of the volume are taken up with the discussion, it will be seen that the applicability of Battey's operation is still upon trial.

Prof. Thaddeus A. Reamy, of Cincinnati, explained

his method of supporting the perineum by means of a towel carried around the buttocks and spread out over the seat with its anterior edge on a level with the fourchette, and its ends held tense, during each pain, by two assistants.

Dr. Edward W. Jenks, of Detroit, reported a fatal Cæsarean section, performed by him in Canada on February 27, 1885, after a labor of twenty-four hours, the fœtus being dead, and the forceps and craniotomy having failed. The death in this case would appear to be largely due to the woman having got out of bed upon the floor during her sleep, producing a shock from which she never rallied. In the United States and Canada there have been twenty-nine fatal Cæsarean operations out of thirty-six in the last ten years.

Prof. William Goodell of Philadelphia, reported three cases of "Inflammation of the Parotid Glands following Operations on the Female Genital Organs," in which there were no evidences of septic poisoning. The operations were ovariotomies; the parotitis appeared to be due to metastasis and closely resembled mumps, except that its course was longer, and there was scarcely any rise of temperature.

Dr. Henry F. Campbell presented the subject of the "Genupectoral Posture" in a paper of seventy-five pages, with nineteen illustrations. The reputation of the Society is well sustained, but an addition of new Fellows would be of advantage.

SOCIETY PROCEEDINGS.

CANADIAN MEDICAL ASSOCIATION.

Nineteenth Annual Meeting, held at Quebec, August 18 and 19, 1886.

(Specially reported for THE MEDICAL NEWS.)

THE nineteenth annual meeting of this Association was held in Laval University, Quebec, on the 18th and 19th of August. The meeting was opened, in the absence of the President, Dr. William Osler, by the Hon. Dr. Sullivan, of Kingston.

After routine business and the presentation of the reports of the various Sections, the PRESIDENT-ELECT, DR. T. K. HOLMES, of Chatham, Ont., was introduced, and delivered an address. After referring to the historic and romantic associations surrounding their place of meeting, he spoke of the influence exercised on medicine by the science of biology and its handmaidens, physiology and pathology. He recommended that the preliminary examination should have a more scientific complexion, and that biology should be added to the list of subjects required for examination. It is most important that the student, before entering on the study of medicine, should have some knowledge of minute organisms. He also alluded to the great importance of endowments in connection with the more purely scientific subjects taught in medical schools. Men holding these chairs could then be properly paid, and would be able to undertake original investigation free from the anxieties of practice. He advised practitioners to belong to local societies, and to keep careful notes of all the cases coming under their observation. In this connection, he observed that it is not necessary for a man to practise in a large centre, or to be connected with a school, in order to do work. Jenner, McDowell, and Koch have been country practitioners. In conclusion, he advised the establishment of lectureships in connection with the Association, similar to those existing in the old world; and after hoping that the meeting would be a successful one, he predicted great things for the medical future of Canada.

OFFICERS ELECTED FOR NEXT YEAR:

President.—Dr. J. E. Graham, of Toronto.

Vice-Presidents.—For Quebec, Dr. Russell; *for Ontario*, Dr. Dupuis; *for Nova Scotia*, Dr. Wickwire; *for New Brunswick*, Dr. Currie; *for Manitoba*, Dr. Crowther.

Local Secretaries.—For Quebec, Dr. J. Bell; *for Ontario*, Dr. McKeough, *for Nova Scotia*, Dr. Trueman; *for New Brunswick*, Dr. Lunam; *for Manitoba*, Dr. Kerr.

Place of Next Meeting.—Hamilton; Chairman of Committee of Arrangements, Dr. Malloch.

SURGICAL SECTION.

WEDNESDAY, AUGUST 18TH.

DR. GEORGE E. FENWICK, OF MONTREAL, IN THE CHAIR.

DR. DESJARDINS, of Montreal, read a paper on

KERATOSCOPY AS A MEANS OF DIAGNOSIS IN ASTIGMATISM.

After defining the term astigmatism, he said that errors of refraction affect the vision injuriously, although the optic nerve be healthy. It was formerly supposed that the fault was in the lens, but it is now known to be due (as was first pointed out by Donders) to the curves of the cornea. The lens, according to later investigators, partakes of the same deformities as the cornea. Accommodation is not without influence on refraction. After mentioning that corneal anomalies are detected by the keratoscope, Dr. Desjardins exhibited and described an instrument of simple construction made by de Wecker and Masillon, by which the meridians and amount of astigmatism can easily be determined. Many cases of slight astigmatism can be rapidly detected and suitable glasses prescribed. By the aid of this instrument, one scarcely needs to submit the patient to a subjective examination, and for this reason the author finds it especially useful in children.

DR. JAMES BELL, of Montreal, read a paper on

TRACHEOTOMY IN MEMBRANOUS LARYNGITIS,

in which he advocated dispensing with the tube in the after-treatment of tracheotomy. He said that the methods of stitching the cut edge of the tracheal to the edge of the neck wound and the nose of the canula had proved of but little benefit in actual practice.

He preferred late to early operations in membranous laryngitis for the following reasons, viz.: (1) If patient were operated on early, many would be operated on unnecessarily; (2) Extension of membrane takes place more rapidly after tracheotomy; (3) If the obstruction is not rapidly produced, membrane is separated and expelled. The recoveries after early operations were 25–33 per cent.; after late operations, 5–10 per cent. A greater percentage recover without operation. He next entered on the question as to whether the extension of

the membrane is due to general or local causes, and thought that the weight of opinion is that extension is due to purely local causes, and gave a number of cases illustrating this point. After discussing the subject as to whether diphtheria is or is not primarily a local disease, he gave his reasons for not liking the tube in tracheotomy: (1) The tube never accurately fits; (2) When the tube is in place, the incisions into the trachea cannot be kept under observation; (3) Occasionally the tube, from not being in the middle line, and being left too long in the trachea, ulcerates through, and an artery may be opened; (4) When the tube is in the trachea, there is difficulty in expelling through it pieces of membrane; (5) The tube causes sometimes exuberant granulations and warty growths. In place of the tube, Dr. Bell has devised an instrument which he thinks does away with the objections to the tube. It consists of a pair of "clips," which catch the edge of the trachea and hold it apart. They are held in position by a tape which goes round the neck. He had experimented with the clips in a number of dogs, and found that they held well and that no ill results followed.

In speaking of the place of operation, Dr. Bell stated that he preferred the low operation, because there was more room, and also because, by it, we get further away from the disease. In the after-treatment of cases in which the "clips" are used, he withdraws the mucus, etc., from the trachea by means of a glass pipette. He said he did not believe in the close camp bed which is now so often used, but preferred a free current of air. After operation he plugs the trachea or larynx above the wound with antiseptic sponge; this absorbs the discharges and helps to localize the membrane. Over the wound he keeps a piece of gauze, and he occasionally introduces vaseline into the trachea. When the tube is used, after two or three days the breathing becomes dry, and the end of the tube becomes coated with inspissated mucus; below this, in the trachea, is a cone of dried exudation, which helps to block up the passage.

Dr. Bell gave the histories of two cases of diphtheria in which he had operated and used his "clips." One case died, and the other—aged twenty-five months—recovered. In nine cases of tracheotomy in which he has used the tube, all, with one exception, died.

He summed up by saying that the excessive mortality after diphtheria was due to defects in the after-treatment. The presence of a tube is a source of irritation and prevents the application of remedies to the trachea itself.

Dr. A. L. Smith, in the discussion which followed, said that when house surgeon to a children's hospital in London, he had a large experience with cases of tracheotomy. He believes that the "clip," introduced by Dr. Bell, will prove of the greatest possible benefit and will in all probability reduce the mortality after the operation. He had seen one death from ulceration of the tube into a large vein.

Dr. Kerr, of Winnipeg, said that he had considerable experience in tracheotomy whilst in Nova Scotia. He had performed it twelve times, and never had a good result. He did not think that tracheotomy is a good operation, and had seen most desperate cases recover without it. If Dr. Bell's treatment without a tube reduced the mortality, it would be a great gain. Dr. Kerr went on to say that the after-treatment of tracheotomy is always a source of anxiety; the tube is apt to get displaced during fits of coughing. In his last case he dispensed with a tube and stitched the edge of the cut trachea to the edge of the wound, as recommended by Post. He did not like this method, for when the patient's chin was depressed, the opening closed. He thought that with Dr. Bell's instrument he could do better. As to the question of the general or local origin of diphtheria, it was too large a subject to discuss at the present time. His last tracheotomy case lived three weeks and died of paralysis, so that it is not always the extension of the membrane that kills after tracheotomy, and the best after-treatment will fail to produce a good result. He was very doubtful about the good that would result from plugging the trachea above the wound.

Dr. F. J. Shepherd said that he had performed tracheotomy a number of times both in hospital and private practice. His first ten or a dozen cases were all fatal, but during the last two and a half years he had performed tracheotomy in private practice sixteen times, and had had five recoveries. In hospital practice his results were not so good. He thought that the kind of instrument used did not matter much; it was important that the wound should be kept aseptic. He removed the tube as early as possible, never later than the fifth day, in one successful case he removed the tube on the third day; they were all cases of diphtheria. He preferred the low operation because the trachea is opened at a greater distance from the disease, there is more room, and it is not necessary to cut the cricoid cartilage. In the high operation division of the cricoid had to be frequently undertaken and often resulted in necrosis. Again, stenosis more frequently occurred after the high operation. Dr. Shepherd believed that after operation it was useful to have a warm room (75°–80° F.), and that the atmosphere should be saturated with moisture. He always used a croup or closed bed, and the steam of the kettle was conveyed into it by a huge spout. The inner tube was removed every hour and the outer one on the second day, lime-water was occasionally dropped into the tube. He thought that the tube favored expulsion of membrane. With regard to the antiseptic plugging of the trachea, he did not think it of much benefit. Very often the membrane extended, at the time of the operation, below the wound, and if it did not, the continuity of the mucous membrane could not be interfered with. He had never seen the conical plug in the trachea described by Dr. Bell. All the cases of death after tracheotomy he had seen had been due to extension of the membrane. Theoretically Dr. Bell's instrument was perfect, but it remained to be seen what it would do in practice.

Dr. Russell, of Quebec, had not seen half a dozen cases of diphtheria in twelve years, but during the last year he had seen a great many cases of membranous croup. He thought this disease was more fatal than diphtheria. He was formerly opposed to tracheotomy, but now thought early operation advisable; if the operation did not cure, it always relieved. He had performed tracheotomy six times with two recoveries. He thought Dr. Bell's instrument was a most ingenious one, and likely to prove very useful. In the after-treatment he was strongly in favor of using lime-water spray.

DR. FENWICK, of Montreal, said that he preferred the high to the low operation. Dr. Bell's instrument appeared to answer very well. Dr. Marshall Hall, many years ago, devised a somewhat similar instrument made of wire. He had seen one of Dr. Bell's cases treated with the "clips," and formed a most favorable opinion of the instrument.

DR. FENWICK, of Montreal, read a paper on

TREATMENT OF TUBERCULOUS GLANDS OF THE NECK.

He believed that scrofulous glands are intimately connected with tubercle. After giving a sketch of the history of tubercle and Koch's discovery of the tubercle bacillus, he said that there must be some predisposing condition in the individual so that he can contract tubercle—the proper soil must be present. The glands of the neck are specially liable to infection, especially the submaxillary and those over the large vessels. Enlargement is rarely single and occurs generally at first on one side of the neck only. Often there are no external signs of softening of the gland, but when the glands break down and open externally indolent ulcers and sinuses are left. The disease generally first shows itself in a single gland and then spreads to other parts; very little is known of the mode of entrance of the tubercle bacillus. In scrofulous enlargement of the glands of the neck the author strongly advised early removal of enlarged glands. After removal the general health of the individual improves; if they are left, the patient runs the risk of general tuberculosis, and if he recovers it is with impaired health and a number of disfiguring scars on the neck. The author preferred removal to laying open and scraping out the gland or the cautery puncture of Mr. Treves. He related a number of cases in which he had removed large numbers of glands from the neck. In his first case, which was operated on in 1873, he removed some half dozen glands from the neck beneath the sterno-mastoid; the scar was now hardly to be seen. Dr. Fenwick showed a number of photographs of cases, before and after operation, where the results were most admirable, the cicatrices being hardly perceptible.

DR. KERR, of Winnipeg, said that if we accepted the principle of the identity of scrofula and tubercle much confusion would be removed. He was not satisfied with the results of operations and did not now operate so often as formerly; he found the operation not only very tedious but difficult and dangerous, and the results were not always so good as represented. Dr. Alexander, of Liverpool, who formerly operated some twelve years ago very frequently in these cases, has now given up the operation.

DR. SHEPHERD, of Montreal, confessed that the results of operation were not always so perfect as were described by the enthusiastic advocates of the operation, but in many cases the results are entirely satisfactory. Occasionally there are high temperatures after operation; sometimes attacks of cellulitis. He had operated in a good many cases, and had removed as many as twenty to thirty glands at a time. Apparently solid glands not infrequently come to pieces during removal, and are found to be quite soft in the centre. These conditions always complicate the operation. After incising the deep fascia, he prefers removing the glands with the fingers, and an occasional cut with a knife. He has never had any accident attending the operation. Although he has had no experience with Treves's cautery puncture, he does not think it suitable for glands deeply placed. In sinuses and scrofulous ulcers, he has had most excellent results from scraping out the parts with Volkmann's spoon.

DR. TRENHOLME, of Montreal, read a paper on

SOME DETAILS OF UTERINE AND OVARIAN OPERATIONS.

He said the instruments used in these operations need not be numerous or complicated. After describing the usual precautions that should be taken regarding the cleanliness of hands, sponges, and instruments, he said that he prefers No. 1–20 shoemakers' thread to any other form of ligature. Before use the thread should be immersed for twenty-four hours in pure carbolic acid, and not put into water at all. In closing the abdominal wound, he uses silver wire for the deep sutures and horsehair for the superficial. He laid great stress on the importance of not enclosing any muscular tissue in the suture. The incision should be midway between the umbilicus and pubis, and should not extend to within one and a half inches of the pubis. He advised short incisions of two to two and a half inches. Muscle should never be cut in the incision, as it gave great trouble afterward.

The pedicle of the tumor should be ligated in small segments, and the large vessels should be ligatured separately and the ligature cut short. The cavity of the abdomen should be thoroughly cleansed with sponges, and drained when necessary. He objects to abdominal bandages, and has only used them after the removal of the largest tumors. He allows his patient after the operation to move freely in bed; this favors the reposition of the bowels. In uterine fibroids, when large, he always divides the mass in the median line, then each half is enucleated. The stump should be cut in shape of a V, and the edges brought together with a running suture and quilted with the shoemaker's stitch. He has found linseed-tea enemata of great service after operation; fomentations to the abdomen were also very beneficial. No after medicinal treatment is needed, except when there is vomiting; in this he has found sipping hot water useful, and also ipecacuanha in homœopathic doses. He uses the third dilution.

DR. MACFARLANE, of Toronto, would have liked to hear Dr. Trenholme say more about dietetics. In his operation he had found vomiting to be a very troublesome complication; warm water with a flavoring of brandy he had found of great service in these cases, also frequent small doses of epsom salts as recommended by Lawson Tait. He never gave any medicine at all when there was any threatening of peritoneal trouble. He never used drainage unless the adhesions were extensive.

DR. SHERMAN, of Ogdensburg, would like to have heard more details regarding the preparation of the patient, also as to whether he referred, when speaking of fibroids, to extra- or intra-mural growths.

DR. MACDONALD, of Wingham, Ontario, would like to have heard more details as to the closure of the wound and also as to the value of the clamp in securing the pedicle and whether operation for ovarian tumors should be performed early.

DR. KERR, of Winnipeg, had seen hernia follow the

operation, due to failure of union in central portions of wound. He would like to know why Dr. Trenholme objected to including muscle in his sutures.

Dr. Shepherd, of Montreal, thought that wounds of the abdomen are much the same as wounds of other parts, and that abdominal surgeons make a great ado about their special methods of healing this abdominal incision. General surgeons who are operating every day in every part of the body have no fear of including muscle in their sutures. He did not understand why an abdominal wound should heal so differently from wounds in other parts. So far as he himself was concerned, in performing abdominal section he treated his incision as an ordinary wound. He used silk or catgut sutures and passed them through the whole thickness of the wall of the abdomen; union invariably took place by first intention. Every gynecologist thinks it incumbent upon him to have some special mode of treatment of the abdominal incision, and seems to think that general surgical principles are not applicable to it. Dr. Shepherd had not much faith in ipecac used in the third dilution.

Dr. Fenwick said that he had operated a number of times for ovarian tumors with fair success. He agreed with the remarks of the last speaker. He always used silk sutures and objected to horsehair because knots made in it did not hold well. In treating the pedicle he first clamped it and then tied all the large vessels; afterward, he tied the pedicle with the Staffordshire knot and removed the clamp. He had used hot water occasionally to cleanse the abdomen.

Dr. Trenholme, in reply, said he spoke of interstitial fibroids. He formed the pedicle out of the labial borders of the uterus in such a way that he left the broad ligaments to sustain the pelvic viscera. He used the shoemaker's stitch to secure primary union. With regard to the external wound, he thought that the conditions found in the abdominal cavity existed nowhere else. It is of the greatest importance to secure primary union so that there shall be no subsequent hernia. For vomiting he used hot water over the wound, and ipecac in minute doses. In preparing the patient he avoided purgatives as much as possible. In cold weather he kept the extremities of the patient wrapped up in cotton-wool.

Dr. Shepherd, of Montreal, next read a paper on

Excision of the Tarsus in Tuberculous Disease of the Bone.

He commenced by saying that formerly when there was carious disease of the bones of the foot the only resource was amputation, but with the advent of antiseptic surgery and the establishment of conservative principles of treatment, other methods of procedure have been adopted with success.

In cases of tuberculous and carious disease of bones the necessity for amputation is not immediate, and it is the duty of the surgeon to endeavor first to remove the local disease before sacrificing the foot. It is not necessary to perform a Hey's, Chopart's, or Syme's amputation in these cases, but merely to remove all the disease, however extensive. The reader of the paper illustrated this principle by giving the histories of several cases. In one case, where there was disease of both feet, he removed on the right foot the cuneiform, scaphoid, cuboid, and bases of the metatarsal bones, and on the left the lower end of the tibia, astragalus, part of the os calcis, the scaphoid, and cuboid. The result was excellent, and the patient, a girl, aged seventeen, was able to walk about comfortably. In children it is often sufficient to remove the diseased portion with a Volkmann's spoon, and in them amputation is hardly ever required.

Dr. Macfarlane, of Toronto, had followed out the principle advocated by the reader of the paper for years. He believed it is the proper method of treatment and should be extended to caries of the spine. In dressing the wound left after excising tarsal bones he never stuffed the wound with anything, but placed the foot in a good position and left the rest to nature.

Dr. Dupuis, of Kingston, said he recently had a case of disease of all the tarsal bones in which he performed amputation; afterward the tibia necrosed and he had to reamputate. He also reported a case of frost-bite in which he had removed the greater part of the tarsus.

Dr. Holmes, of Chatham, remarked that Dr. Shepherd's paper was a good exemplification of conservative surgery. He had several times excised the ankle-joint with the best results.

Dr. Kerr, of Winnipeg, said that patients, after operation, should not be allowed to walk about too soon, as they were apt to have a splay foot. He did not believe in leaving the wound to nature altogether, but preferred keeping it in an aseptic condition.

Dr. Russell, of Quebec, also insisted that the wound should be carefully protected and that antiseptic dressings should be applied. If the wound were left to nature, it would soon become putrid and all the dangers incident to such a condition would be incurred.

Dr. Fenwick said he could mention a number of cases in which he had resected the tarsus with the happiest results. He related the case of a gentleman (a medical man) who had been wounded at the battle of the Alma, and had carried the bullet in his heel for nearly thirty years. The os calcis was trephined, and the bullet removed, with result of a rapid closure of the cavity and a useful foot.

Dr. Kerr, of Winnipeg, read a paper on the

Evacuation of an Abdominal Hydatid Cyst.

The patient was an Icelander, who came into the Winnipeg Hospital last winter with a large abdominal tumor. From the history, and as the result of exploratory puncture, the attending physician, Dr. Whiteford, made the diagnosis of hydatid cyst, and handed the case over to Dr. Kerr, for operation. The operation was performed in two stages, as recommended by Volkmann. A cut was first made down to the growth, and six days after it was incised. To open the cyst, he had to cut through two inches of the liver. The cyst was then emptied, and washed out with a solution of iodine. The patient did well, and went home in two months. He remarked that these are rare cases. Up to 1880, only 155 cases have been reported. This is the second case that has been seen in the University Hospital. The other patient was operated on, but died on the table.

Dr. Eccles, of London, Ont., related the history of a case which had been treated a year ago in the London Hospital.

THURSDAY, AUGUST 19TH.

DR. KERR reported two cases of

GUNSHOT WOUND OF THE HIP-JOINT.

Both cases were caused by the accidental discharge of small shot. The soft parts were much torn, the trochanters in both cases were split and the joints laid freely open. In the first case the patient was not seen till three weeks after the accident, and had had no treatment; his condition was deplorable. The whole wound was in a sloughy condition, and horribly fetid. The patient was in a septic condition. The wound was thoroughly cleansed, the sphacelated portions freely excised, and the wound irrigated and packed with iodoform gauze; an anterior wire splint was also applied. The improvement at first was marked, but the patient died of septicæmia and exhaustion in a short time. The second case was seen immediately after the accident; the wound was treated in the same way, and the limb fixed in an anterior Smith's splint; a posterior splint was also employed, so that immobility was secured, and recovery with a useful limb resulted. Dr. Kerr referred to other methods of treatment, viz., excision and amputation. In these cases the mortality was high. He brought these cases before the Section in order to show what could be done by conservative methods in such cases.

DR. CLARKE, of Toronto, said that a number of cases of gunshot injuries of the hip were reported in the *Surgical History of the American Rebellion*. He had seen several cases treated when with the Federal army in Virginia. They were treated under canvas, and did well.

Drs. Russell, Fenwick, and Shepherd also joined in the discussion.

DR. BULLER, of Montreal, read a paper on

THE TREATMENT OF ACUTE PURULENT OPHTHALMIA.

He remarked that eyes are now seldom lost in these cases. Some use hot applications, others cold; some use astringents, others do not; some use antiseptics, others rely on frequent and thorough washings. All are agreed on the necessity of frequently cleansing the diseased eyes. Many remedies are used, as quinine, boracic acid, corrosive sublimate, etc. The antiseptic treatment is still on trial. Solutions used as germicides must be strong, weak solutions are of little value as antiseptics. He had lately treated three cases of acute gonorrhœal ophthalmia. He first used boracic acid and afterward a solution of corrosive sublimate, the latter in the strength of 1 : 2000 without improvement, but the application of a solution of 1 : 1000 was followed by immediate and marked improvement. The patient was discharged cured in twenty-four days. In the other case the patient was a child, aged three years, with acute vaginitis; under similar treatment patient rapidly recovered.

In the third case, also one of gonorrhœal ophthalmia, there was sloughing of the cornea. He treated it by hot fomentations and washes of boracic acid and sublimate solution used warm. Improvement immediately followed, the slough separated and a clean ulcer was left which soon healed.

Dr. Buller thinks that in general practice a rigid cleanliness is not sufficiently carried out. With regard to cold applications, he thinks they are the best, but whilst applying them the cornea should be closely watched; if there is any cloudiness, hot applications should immediately replace the cold, and the cornea will be saved.

Drs. Smith, Russell, and Fenwick took part in the discussion which followed.

DR. SHEPHERD, of Montreal, read the notes of a case of

AINHUM,

which he had treated in the Montreal General Hospital. The disease affected the little toe of the right foot of a negro, æt. forty-seven, born in North Carolina. The little toe became affected some six years before. He first noticed a small ulcer on the digito-plantar fold, then a constriction surrounded the toe at this point which gradually deepened. The toe was much larger than normal. He suffered greatly when walking. The toe was amputated and on dissection appeared to consist of much thickened skin and fibrous tissue. The bones of the toe were much atrophied and the joint had disappeared; the proximal phalanx looked somewhat like a claw. The reader of the paper then gave a short sketch of the history of the disease, saying it was first accurately described by Dr. Silva Lima, of Brazil, that it was a disease confined to the dark races, and was more common in some families and more in men than women. It sometimes affects the fingers and even limbs. The disease, if left to itself, lasts about ten years and ends by amputating the member affected. The word "ainhum" is a negro word, and means "to saw."

DR. FENWICK, of Montreal, reported a case of

AMPUTATION AT THE SHOULDER-JOINT FOR MYELO-SARCOMA OF THE ARM.

Patient, a woman, aged forty-seven years, seven months pregnant, came to Montreal General Hospital in the spring of the present year, with a large ulcerated tumor a little below the shoulder of the right arm, and a smaller tumor near the biceps. Two years ago she had received a blow, and within three weeks perceived a small lump at the site of injury. It grew rapidly and was removed. She was told that it was a fatty tumor. It soon returned, and this time plasters were applied by a "cancer doctor," which burnt the tumor, and caused the ulcerated appearance which was seen when admitted to hospital. Dr. Fenwick amputated the arm at the shoulder-joint, and patient did remarkably well, never having a temperature higher than 99° F. On examination, the tumor proved to be a myeloid sarcoma. This was the first case Dr. Fenwick had seen in which the myeloid tumor first affected the tissues external to the bone and periosteum.

DR. A. LAPTHORN-SMITH read a paper on

ALEXANDER'S OPERATION, AND THE TREATMENT OF DISPLACEMENTS OF THE UTERUS.

After describing the operation minutely, and also giving a discourse on the anatomy of the parts, Dr. Smith went on to say that the round ligaments are really muscles, and are not in a state of tension, except during coition. They are the homologues of the cremaster muscle in the male. Dr. Smith considered that the risks of the operation are great, and that it is not a justifiable one, except in extreme cases, and

when performed did not permanently cure displacements of the uterus. He prophesied that it would soon fall into disuse. The author said that displacements of the womb could be corrected by lessening congestion, by keeping the liver clear and the lower bowel empty. The paper was illustrated by diagrams and tables.

Dr. Trenholme agreed with Dr. Smith that the operation was one that would soon be known only in history. He had operated once, but had failed to find the ligament. He himself, many years ago, suggested a similar operation.

Dr. Shepherd had frequently dissected the round ligament, and had performed operations on the dead subject. The uterus could be easily elevated by pulling on the ligaments. He did not think the fact that a few muscular fibres had been found on the ligament proves that it is now in active use as a muscle; it is, rather, a fœtal remnant of the ligament of the Wolffian body, and the homologue of the gubernaculum testis of the male.

Dr. Ahern, of Quebec, said that the round ligament is frequently abnormal, and that at its insertion is often much atrophied. In cases where the uterus is fixed, tightening it will not correct displacements.

The Section then adjourned.

CORRESPONDENCE.

WESTERN DRESSED BEEF.

To the Editor of The Medical News,

Sir: Possibly it might be of interest to the readers of The Medical News to hear something on the subject of a healthy beef supply.

I have been spending some time on cattle ranches of the Dakota Bad Lands, and became particularly interested in the results obtained by the Northern Pacific Refrigerator Car Co. Its president, the Marquis de Mores, has planned most skilfully, after years of practical study, a very complete system of killing and packing beef on the cattle range, and delivering it in perfect condition to the retail shops of the Company in New York. From a description of his methods it can be seen how well the element of healthfulness is preserved to the product. Others are following similar plans to the great gain of the consumer.

The question how to get clean meat—meat free from the many evil effects incident to transportation—seems to be solved by killing and dressing the beef in or near its natural home, and sending it direct to the shops. The grave importance of this is awakening much wholesome discussion among thinking people, and should be especially considered by the teachers of preventive medicine.

I need not enlarge upon the manifold opportunities for disease and injury to live cattle during transit. These are obviously many, and certain to occur, varied by accidents and the weather. In transit to the Eastern market cattle are upon the train for about ten days, huddled together as closely as possible, terrified, ill fed, consumed with thirst and fatigue. The gross shrinkage on each steer is estimated at ten per cent. of its actual weight. To this must be added ten pounds of bruised flesh trimmed away. The skilled pathologist alone can describe the wretched state of the organs of such creatures, and the consequent unfitness of their other tissues for human food. On the other hand, that animal which can be driven comfortably from its customary feeding grounds to a properly equipped slaughter-house, killed, and dressed under favorable conditions, and the flesh forwarded direct to the consumer surrounded by uniform conditions of temperature and dryness, is surely better qualified to fulfil its destiny as food.

The plan pursued by the Marquis de Mores is, in outline, this: He takes the cattle from his own ranges lying hereabout, and after a drive of a few miles allows them to rest for a day or two. They are then killed, in such numbers as his retail shops demand, by a process of "pithing." A powerful spear is driven from above through the junction of the medulla and cerebellum. Death is instantaneous. They are at once dressed in a very large airy room; the carcass thoroughly cleaned, and placed in a cooling room for forty-eight hours at a temperature of about 38° F. By an ingenious arrangement of ventilation this room is maintained in so dry and clean a condition that the meat becomes actually dry to the touch. The gaseous exhalations, etc., are precipitated into the melting ice, whence they are carried in solution. In this room one can strike a match on almost any surface, so complete is its dryness, and the air is practically free from any odor. At the end of forty-eight hours the carcasses are packed in the refrigerator cars, models of cleanliness, at a lower temperature than that of the packing-room —about 34° F., and the cars are very carefully maintained at this temperature till they have arrived at the shops of the Company in the East for distribution directly to the householder.

In this way the eleven middlemen, through whose hands cattle usually pass before the dressed meat reaches the cook, are dispensed with. The financial aspect of the enterprise bids fairly for success, and the beef is certainly of better quality than that which is so unfortunate as to be much handled. The shops referred to have a limited capacity, and all beef is sold out at once at very reasonable rates. This enables the Company to maintain a steady and accurate rate of production. The details of this enterprise are of great interest, but I have said enough to give your readers an idea of how clean, wholesome beef can be had at a low cost.

Yours respectfully,

J. Madison Taylor.

Medora, Dakota, August 15, 1886.

SIMPLE METHOD OF ADDING NITRIC ACID TO URINE IN TESTING FOR ALBUMEN.

To the Editor of The Medical News,

Sir: In your issue of July 24th, on pp. 96 and 97, I notice that the "Albumen Test Committee," in their report to the Clinical Society of London, favor the use of nitric acic in testing for albumen and describe nitric acid "as being most reliable and delicate."

In no work on urinalysis, nor in any of the journals, have I seen mentioned the following method of adding nitric acid to the urine, and this method I have employed for some time.

We must first bear in mind that the specific gravity of normal urine ranges from 1.015 to 1.022, though some authors place it as low as 1.005 and as high as

1.030. Now the specific gravity of nitric acid (U. S. P.) is 1.420 and dilute nitric acid (U. S. P.) is 1.059, each being greater than that of normal urine. To test the urine for albumen, pour into a test-tube of medium size enough urine, so that there shall be a column 2 or 2½ centimetres in height; then with a pipette or small tube take up a column of nitric acid 3½ centimetres in height, or, in general, let the column of acid be a little higher than the column of urine (so better to notice the displacement of the fluids). With the finger firmly pressed against the upper end of the pipette or tube, pass the latter to the bottom of the column of urine still keeping the finger pressed against the upper end; the fluids will mix according to the force of their specific gravity—*i. e.*, the nitric acid will gradually flow to the bottom of the test-tube and the urine will rise in the tube to the height at which was the nitric acid. By this method we can more easily and more clearly notice any turbidity which may be formed and without any agitation of the fluids. The same method can be followed in using acetic acid (U. S. P.) which has a specific gravity of 1.048, or the glacial acetic acid which has a specific gravity of 1.056–1.058.

Respectfully yours,

E. H. Trowbridge, M. D.

601 Congress St., Portland, Me.,
August 18, 1886.

NEWS ITEMS.

Dr. Oliver Wendell Holmes sailed from Liverpool last Saturday on the steamship "Aurania," and is expected in New York to-morrow.

The University of the City of New York has conferred the honorary degree of M.D. upon Mr. Lawson Tait.

Americans at the Meeting of the British Medical Association.—Among the Americans registered as present at the meeting, we notice the names of Drs. T. A. Emmet and Fordyce Barker, of New York; J. S. Billings, of Washington; Wm. Brodie, of Detroit; J. R. Chadwick, of Boston; N. S. Davis, of Chicago; Frank Donaldson, of Baltimore; Chas. Warrington Earle, of Chicago; H. O. Hitchcock, of Kalamazoo; F. H. Hooper, of Boston; Howard A. Kelly, of Philadelphia; W. T. Lusk, of New York; Hunter McGuire, of Richmond; R. B. Maury, of Memphis; W. H. Pancoast, of Philadelphia; W. F. Peck, of Davenport, Iowa; S. J. Radcliffe, of Washington; H. P. C. Wilson, of Baltimore; James C. Wilson, of Philadelphia; and W. Gill Wylie, of New York.

The Volta Prize.—The Volta prize of 50,000 francs will be awarded by the Paris Academy next year for the most worthy discovery in the province of electrotechnics in its application to chemical, technical, or therapeutic uses. The theses must be presented by June 30, 1887.

The Brighton Prize of two hundred dollars for the current year has just been awarded, by the committee appointed for that purpose by the President and Fellows of Harvard University, to Dr. Charles F. Withington, of Boston, for an essay on "The Relation of Hospitals to Medical Education."

The Liebig Monument Fund amounts to 25,000 dollars, and the monument will be erected in Ziessel, a small Hessian University town, where Liebig first won fame as a lecturer on chemistry.

Dangerous Lemonade.—A style of lemon-squeezer has been recently sold quite extensively which is made of galvanized iron, or iron covered with a coating of zinc. A word of caution should be given against the use of such articles, as the citric acid of the lemon will readily dissolve the zinc, forming unwholesome and poisonous salts. Lemon-squeezers should be made either of plain iron or wood, or, better, like some we have observed, where the surfaces brought into contact with the fruit are of glass or porcelain. Zinc is a metal which is readily attacked by the weakest acids, and no article of food or drink should ever be allowed to come into contact with it.

To Distinguish Oleomargarine from Butter.—J. Horstler recommends the following procedure: A piece of oleomargarine the size of a hazelnut is placed in a test-tube, and the end made air-tight. Into another test-tube a like quantity of butter is treated in the same way. When both test-tubes are held in the hand, the oleomargarine soon liquefies, forming a clear solution; whilst butter requires double the time for solution, and when dissolved is not so clear as the oleomargarine solution. When the tube is filled one-third full with ether, the oleomargarine is easily dissolved, and does not produce any turbidity or precipitate on the addition of alcohol. Butter when treated in like manner yields a precipitate.

American Public Health Association. — The Fourteenth Annual Meeting of the American Public Health Association will be held at Toronto, Ont., Oct. 5–8, 1886. The Executive Committee have selected the following topics for consideration at said meeting:

I. The disposal of the Refuse Matters of Cities and Towns.

II. The Condition of Stored Water-supplies, and their Relation to the Public Health.

III. The Best Methods and the Apparatus Necessary for the Teaching of Hygiene in the Public Schools, as well as the Means for Securing Uniformity in such Instruction.

IV. Recent Sanitary Experiences in connection with the Exclusion and Suppression of Epidemic Disease.

V. The Sanitary Conditions and Necessities of School-houses and School-life. (See Lomb Prize Essays.)

VI. The Preventable Causes of Disease, Injury, and Death in American Manufactories and Workshops, and the best Means and Appliances for Preventing and Avoiding them. (See Lomb Prize Essays.)

VII. Plans for Dwelling-houses. (See Lomb Prize Essays.)

All persons who propose to present papers at the next meeting of the Association will be governed by the following order, enacted by the Executive Committee at Washington, D. C., Dec. 7, 1885: "That all papers hereafter presented to the Association must be either printed, type-written, or in a plain handwriting, and be

in the hands of the Secretary at least twenty days prior to the annual meeting."

The International Medical Congress and the British Medical Association.—At the meeting of the Council of the British Medical Association held on Tuesday, August 10, the following letter was read from representatives of the Organizing Committee of the International Medical Congress, requesting facilities for communicating with the members of the British Medical Association on the subject:

"We, the undersigned Officers and Members of the Executive Council of the International Medical Congress, to be held in Washington, U. S. A., on the 5th to 11th of September, 1887, desire to take this opportunity of communicating to members of the medical profession in Great Britain, and especially to members of the British Medical Association, some of the arrangements for the reception at that Congress, and to extend to them a cordial invitation to visit our country and to attend the Congress.

We shall be greatly obliged to you, and to the Council of the British Medical Association, if you could afford us facilities for this purpose; and we would ask of your courtesy to allow us the use of a room in the Pavilion, at a stated hour on Thursday next, if convenient, for the purpose of meeting members of the Association, to whom we could make a statement on the subject.

We are, Dear Sir, Your faithful servants,

N. S. Davis, M.D., LL.D., President of the Preliminary Organization of the Ninth International Medical Congress, and member of the Executive Committee, and Ex-President of the American Medical Association.

Wm. Brodie, M.D., Vice-President of the Congress, and late president of the American Medical Association.

Wm. H. Pancoast, M.D., etc., Vice-President of the American Medical Association; Member of the Executive Council of the International Congress, 1887.

Wm. C. Wile, M.A., Vice-President of the American Medical Association."

On motion, it was resolved "that the request be granted."

Sir James Paget and the International Medical Congress.—*The Lancet* having announced, in its issue of Aug. 7, that Sir James Paget was likely to attend the Washington Congress, says in its issue of the following week that it was in error in so stating. It, however, "still hopes that one who would be so much missed will find his way to Washington."

Liquids by Mail.—The decision of the Postmaster-General recently promulgated, admits to the advantages of mail carriage and distribution many articles heretofore forbidden. The following abstract of Order No. 135 will be sufficient to exhibit the scope and the excellent provisions of the new regulation:

Liquids and oils (not to exceed four fluidounces), pastes, salves, or articles easily liquefiable must be enclosed in a wooden or *papier maché* block, not less than three-sixteenths of an inch thick in the thinnest part, strong enough to support the weight of mails piled in bags and resist rough handling. Between the bottle and the block must be some absorbent, such as cotton, felt, asbestos, cork crumbs, in order to prevent damage to other parcels. The top of the block must have a metal or wooden screw lid fitting tightly and have rubber pads. Articles not liquid must be placed in a bag, box, or removable envelope or wrapping made of paper, cloth, or parchment, and placed within a box or tube of metal or wood with sliding clasp or screw lid. If the articles are liable to break, there must be some elastic packing between the inner package and the box or tube in which it is mailed. There are other portions of the regulations which apply to articles which have no special interest to physicians or druggists.

The law will, therefore, permit any ordinary liquids (not ethereal or inflammable) being sent by mail to any post-office in the United States when put up with such care as will prevent their breakage.

Cinchonidine in Quinine.—Recently the well-known quinologist, M. de Vrij, has brought to prominent notice the fact that large quantities of cinchonidine salts were present in some brands of foreign quinine, and his assertions, as contained in a communication made to the Pharmaceutical Society of Paris, caused it to take special action in the matter. A committee was appointed to investigate the facts, and recently the chairman, M. Jungfleisch, presented his report, which fully substantiates the claims of M. de Vrij.

The statement of M. Jungfleisch is that he found market samples which contained 8, 10, 12, and 16 per cent. of cinchonidine. Quinine containing this salt was much more bulky—in fact, it is asserted that all the *light* bulky quinine of commerce is of this characteristic, viz., containing cinchonidine. He, therefore, advises that *all light* quinine *should be rejected*, and contends that *no pure* quinine sulphate can be made having the character of unusually light bulk. Of the intimate connection of these two alkaloids it may be said that their preëxistence together in some barks makes it a difficult matter to separate them at times, and some samples of cinchonidine contained as much as 10 per cent. of quinine.

What New York Drinks.—A recent official report by the New York health authorities states that the Croton water-shed embraces 239 square miles, and has a population of 20,000, with 1879 dwellings and as many privies, about as many barnyards, pig-pens, and cesspools, besides cemeteries, graveyards, slaughter-houses, and other sources of contamination, *and with no drainage except by the surface*, which conducts it to the aqueduct. Yet the Croton is the best water supply enjoyed by any large city in America or elsewhere!—*Sanitary Era.*

Preservation of Fresh Fish.—Of late years we have been accustomed to associate economy in the preservation of food with colonial or transatlantic enterprise. It is, therefore, the more encouraging to learn that Europe is equal to inventive progress in the same direction, and of this we have apparently a genuine proof in the method of preserving fresh fish introduced by Mr. August R. Roosen, of Hamburg. By his process, which is a simple one, the fish when caught are enclosed in steel barrels, each capable of accommodating 300 pounds weight, immersed in a three per cent. antiseptic solution of boracic acid, tartaric acid, and salt in water, which is forced in by means of a hydraulic hand-pump, while air is simultaneously expelled. An air-tight lid

closes the cask, and the bung-hole is a valve to which the pump is attached when in action, and which at a certain stage is closed by internal pressure. It is also satisfactory to find that a year's experience has proved its practical efficiency, at all events in the hands of the introducers. Meat is stated to have been preserved by the same process. On board of the larger fishing craft the plan appears likely to answer well. One or two points in connection with its working will require careful regulation. With regard to the water in which the antiseptics are added. If this is to consist of sea-water, as might naturally be expected, it will still be necessary for coast fishers to be careful as to its purity from river or port refuse. It will also be necessary to guard against the overcrowding of fish. If this should happen, even powerful antiseptics will be of little avail, since perfect exclusion of air is hardly possible. We hope that future use will justify the promise of this novel and ingenious experiment.

REVOLVER BULLET LODGED IN THE BRAIN; RECOVERY.—At the Society of Surgery of Paris, on May 26th, M. Prengrueber presented a man who had fired a revolver at the middle of his temporal fossa. The ball, seven millimetres in diameter, lodged in the brain. The three days following the accident the surgeon abstained from interference, as the only symptoms were general prostration with lowering of the temperature. Epileptiform attacks having occurred on the fourth and fifth days, M. Prengrueber exposed the cranial wound and removed several bony spicules, which had penetrated the brain. A stilet having failed to detect the bullet, though passed along its course to a depth of five centimetres, nothing else was done. The epileptiform seizures did not recur, and the patient left the hospital at the expiration of a month without any cerebral complication.

MUNICIPAL LIBERALITY.—At its sitting of July 31st, the Municipal Council of Paris voted a credit of 289,765 francs (£11,590) for the construction of a new surgical department at the Hôpital Cochin, to replace the wooden huts erected during the siege. It is intended to provide for all the requirements of modern surgery, with laboratory, means of isolation, etc.

MEDICO-LEGAL LABORATORIES IN SPAIN.—The Spanish Ministry of Justice has arranged for the establishment in Madrid, Barcelona, and Seville, of laboratories of forensic medicine. After the middle of September, analyses which may be ordered by magistrates will be conducted in the new institutions—a provision enabling experts nominated in the interests of accused persons to be present during the performance of such analyses.

A USEFUL PLANT—Dr. Brandes, a Hanoverian physician, has recently demonstrated in a German contemporary the valuable properties of the anacharis alsinastrum, a water-plant which has hitherto been considered as an unmitigated nuisance, choking up rivers, and altogether useless. Dr. Brandes has remarked that in the district where he lives, and where malaria and diarrhœa yearly appeared in a sporadic or epidemic form, those diseases have gradually decreased since the anacharis alsinastrum began to infest the neighboring rivers and marshes, and for four years have totally disappeared. He therefore proposes that the plant, which came originally from Canada, should be planted in marshy districts, with the view of checking malaria; and the experiment, in view of the evidence adduced in the article under notice, is certainly deserving of consideration.

NEW JOURNAL.—The first number of *The Review of Experimental and Therapeutic Hypnotism* has appeared in France. It is edited by M. Edgard Berillon, with the collaboration of Barety, de Beauvais, Bernheim, Fränkel, Guys, P. Maginn, Aug. Voisin, and others.

DEATH OF PROF. MAAS.—The death, at the age of forty-four, is announced of Dr. Hermann Maas, Professor of Surgery in Würzburg.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT OF THE U. S. ARMY, FROM AUGUST 17 TO AUGUST 23, 1886.

BAILEY, J. C., *Major and Surgeon.*—Granted one month's leave of absence. *S. O. 111, Division of the Atlantic*, August 17, 1886.

BENTLEY, E., *Major and Surgeon.*—Granted one month's leave of absence, and at its expiration to report for duty as Post Surgeon at Little Rock, Ark.—*S. O. 113, Division of the Atlantic*, August 18, 1886.

LORING, L. Y., *Captain and Assistant Surgeon.*—Leave of absence granted him in S. O. 59, August 2, 1886, Division of the Pacific, extended two months, on Surgeon's certificate of disability.—*S. O. 189, A. G. O.*, August 16, 1886.

TAYLOR, B. D., *Captain and Assistant Surgeon.*—When relieved by Surgeon Bentley, to proceed to Jackson Barracks, La., and report for duty as Post Surgeon.—*S. O. 113, c. s., Division of the Atlantic.*

HOPKINS, WM. E., *First Lieutenant and Assistant Surgeon.*—Assigned to duty as Post Surgeon at Angel Islands, California.—*S. O. 61, Division of the Pacific*, August 6, 1886.

BORDEN, WM. C., *First Lieutenant and Assistant Surgeon.*—Assigned to temporary duty at Fort Boidger, Wyoming, during absence of Assistant Surgeon Crampton.—*S. O. 100, Department of the Platte*, August 9, 1886.

WALES, PHIL. G., *First Lieutenant and Assistant Surgeon.*—Relieved from duty in Department of the Columbia, and to report in person at Headquarters Division of the Pacific for further orders.—*S. O. 62, Division of the Pacific*, August 9, 1886.

MASON, CHAS. F., *First Lieutenant and Assistant Surgeon.*—Assigned to duty as Post Surgeon at Plattsburg Barracks, New York.—*S. O. 113, Division of the Atlantic*, August 18, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING AUGUST 21, 1886.

STONE, DR. E. P.—Commissioned an Assistant Surgeon in the Navy, August 5, 1886.

WENTWORTH, A. R., *Assistant Surgeon.*—Ordered to temporary duty at Navy Yard, League Island, Pa.

LIPPINCOTT, G. C., *Passed Assistant Surgeon.*—Ordered to Annapolis, Md., for temporary duty as member of Medical Examining Board.

THE DIRECT ACTION OF CALCIUM, SODIUM, POTASSIUM, AND AMMONIUM SALTS ON THE BLOODVESSELS.

BY H. G. BEYER, M.D., M.R.C.S.,

PASSED ASSISTANT SURGEON U. S. N.; HONORARY CURATOR, SECTION MATERIA MEDICA, U. S. NATIONAL MUSEUM.

THE experiments of Ringer on the influence of certain calcium and potassium salts on the contractility of the frog's ventricle, have attracted well-deserved attention from the profession.

In the several papers published in the *Journal of Physiology*, he has shown that very minute quantities of potassium and calcium salts possess the power of greatly modifying the contractility of the heart. He pointed out that even so minute a quantity of potassium chloride as 1 in 15,000, and of calcium chloride as 1 in 10,000, is capable of promoting the normal cardiac contractility, provided they are brought in contact with the ventricle in the presence of a three-quarter per cent. saline medium.

Ringer, while not attempting to explain how such minute quantities of inorganic salts can influence so profoundly the organized structures of the heart, thinks it not improbable that the salts do not enter into direct combination with the molecules of the muscular tissue, or, if any combination does take place, that it is of an extremely loose character, since the salts are easily dislodged and washed away by the mere circulation of a fluid devoid of these salts.

Kronecker, and some of his pupils, find that if a ventricle is fed with a 0.6 per cent. normal saline solution, contractility soon ceases, and a strong induction-shock will not excite contractions. They conclude that the suspension of contractility depends on the saline solution washing out all the nutritive material from the cavities of the heart and the meshes of its spongy substance.

Merunowicz (quoted by Ringer) found that the dissolved ash of incinerated blood furnishes a good fluid for supporting the heart's contractility, and Gaule concluded that the essential agent in the ash which sustains the contractility is an alkaline carbonate. Gaule also found that the addition of an alkaline sodium salt, even in small quantity, to saline solution, enables it to sustain contractility longer than when simple saline solution is used.

Gaule, therefore, differs from Kronecker, and maintains that the heart can feed on its own tissues, and derive from them all the materials necessary for a contraction. Kronecker, on the other hand, insists that the frog's heart does not feed on its own substance, and that as soon as nutritive fluid is withdrawn its contractility ceases.

We think that Ringer has shown conclusively that certain alkaline salts will prolong the contractility of the heart, and calcium salts prolong it more than sodium salts. Ringer very correctly observed that the character of the contractions underwent much alteration under the influence of these salts, but that the addition to the circulating fluid of a physiological quantity of a potassium salt entirely obviated these alterations, adding greatly to the duration of the contractility. It was found that while calcium salts promoted the contractility, potassium salts favored the relaxation of the ventricle.

Thus, by adding to normal saline solution certain small quantities of bicarbonate of sodium, chloride of potassium, and chloride of calcium, Ringer finally succeeded in obtaining a circulating medium by means of which normal contractility could be maintained for hours.

On looking over the literature of the subject, I found that very little indeed had been done to ascertain the nature of the action of these salts on the vascular system. The interest and importance which attaches to the results of Ringer's experiments on the heart made it appear very desirable that something more should be done with a view of ascertaining the exact influence of these salts on the vascular system.

With this object in view, the experiments which follow were made.

On account of the great scarcity of frogs in mid-winter these experiments were all made with terrapins. My method consisted in cutting out the heart and inserting canulas into the aortic trunks, and one canula into the sinus. The aortic canulas were connected with Mariotte's flasks, placed at a certain height above the body of the animal, from which flasks liquid was made to flow into the arteries. This liquid, after circulating through the capillaries and veins, was drained off from the sinus into a beaker, and measured at definite intervals. After this outflow had become constant, circulating fluid, plus the drug, was substituted for the normal circulating fluid, and the action of the drug on the vessels determined from the change which took place in the amount of the outflow in a unit of time. A decreased outflow indicated increased resistance to the flow of the fluid through the vessels, or, in other words, a constriction of them, and an increased outflow, a dilatation of them.

In most of my published experiments on the action of drugs on the heart and bloodvessels, I made use of a circulating fluid which I termed "Ringer's saline," on account of his having first proposed it as a good substitute for the normal salt solution wherever the use of the latter might be indicated. As a diluent for mammalian blood to be used in experiments on the isolated heart of cold-blooded animals, it certainly was found to surpass by far the ordinary seventy-five one-hundredths per cent. salt solution in keeping the heart active and alive to the action of drugs as well as to other influences.

But in experimenting with different alkaline salts on the bloodvessels, I was naturally obliged to fall back upon normal salt solution as the standard, and, therefore, the first experiments were made with a view of ascertaining the influence on the bloodvessels of Ringer's saline as compared with that of normal salt solution.

EXPERIMENT XLI.—March 23, 1886. Terrapin 1250 grms. Inflow canulas in right and left arterial trunks. Outflow canula in sinus. Arterial pressure 18 c.m. Venous pressure 0. Circulating fluids: Ringer's saline and normal salt solution (0.75 per cent.).

Experiment XLI. is one out of the three experiments made with regard to the influence of Ringer's saline on the bloodvessels as compared with that of normal salt solution. They all show very clearly that Ringer's saline possesses over normal salt solution the power of greatly contracting the bloodvessels. This contraction, as shown in this experiment, takes place gradually, but the dilatation which follows the readmission of normal salt solution is very slow.

The composition of this fluid is as follows:

Normal salt solution . . .	(0.75 per cent.)	100 c.c.
Calcium chloride solution .	(1 : 390)	5 "
Sodium bicarbonate solution	(0.50 per cent.)	2.5 "
Potassium chloride solution	(1.0 per cent.)	0.75 "

Mix and filter.

The question naturally arose as to which one of the different constituents of this fluid gave rise to the contraction of the vessels. Several experiments were made with regard to this point, but Experiment XLII. will suffice to show that it was the chloride of calcium. As indicated in the heading, three different circulating fluids were made use of: First, normal salt solution; second, normal salt solution to which had been added potassium chloride in the exact proportion in which this was contained in Ringer's saline; third, Ringer's saline, the potassium chloride left out. Potassium chloride, therefore, was used in extremely small quantities, the solution containing less than 1 : 10,000.

This experiment shows very clearly that normal salt solution and potassium chloride give rise to great dilatation of the bloodvessels, while, on the other hand, Ringer's saline without potassium chloride causes their contraction. As may be seen in the experiment, the vessels, contracted by Ringer's saline minus potassium chloride, are gradually dilated by normal salt solution, and this dilatation is still further increased upon the admission of normal salt solution plus potassium chloride. Ringer's saline now readmitted, within a very few minutes may be noticed to reduce the quantity of the outflow to one-third its former amount, therefore, also reducing the calibre of the vessels in about the same proportion; normal salt solution reëstablished the normal calibre of these vessels, while potassium chloride, again, caused them to dilate.

From this and other experiments, all concordant, it is plain that everything pointed to the chloride of calcium as being the cause of the contraction of the vessels, and, at the same time, to the potassium chloride as causing their dilatation. Both having been used in the same proportion in which they are contained in Ringer's saline—that is, in very minute quantities—we may conclude (1) that calcium chloride, even in very small doses, gives rise to contraction, and potassium chloride in equally minute doses to dilatation of the bloodvessels in the terrapin.

EXPERIMENT XLII.—March 24, 1886. Terrapin 990 grms. Inflow canulas in right and left arterial trunks. Outflow canula in sinus. Arterial pressure 18 c.m. Venous pressure 0. In order to test still further the action of lime salts on the vessels, a saturated solution of sulphate of lime was made, and the solution converted into normal salt solution by simply adding the required amount of chloride of sodium. In addition, a solution of bromide of potassium was made containing one gramme of the bromide in 3000 cubic centimetres of normal saline solution. Several observations were made with the solution of bromide of potassium, but since they were all concordant, one will here suffice to show the effect it produces on the vessels.

Experiment XLV. clearly shows the influence of both calcium and potassium salts on the vessels in larger doses than had been used in previous experiments. It was found that under sulphate of lime the quantity of the outflow was gradually diminished to about one-fifth normal, and that, therefore, the calibre of the vessels must have become reduced in about the same proportions. Bromide of potassium, on the other hand, gave rise to an increased outflow, hence must have dilated the vessels.

The conclusions, therefore, are obvious, namely, calcium salts, in comparatively large doses, cause contraction, and potassium salts, in medium doses, cause dilatation of the bloodvessels, in the case of the terrapin.

EXPERIMENT XLV.—March 27, 1886. Terrapin 460 grms. Inflow canulas in right and left aortic trunks. Outflow canula in sinus. Arterial pressure 16 c.m. Venous pressure 0. The observations recorded in Experiment L. show that bromide and iodide of sodium in large doses give rise to dilatation of the bloodvessels, which dilatation is followed by contraction of the same. The same result was obtained when these salts were used in the proportion of 1 : 5000, with the exception that the dilatation produced lasted longer, and the contraction came on much later, and was much more gradual. Sodium salts, therefore, differ materially from those of calcium and potassium in their effects upon the bloodvessels.

Experiment XLVII. shows that bicarbonate of sodium, like bromide and iodide of sodium, causes dilatation of the bloodvessels, which dilatation is followed by a contraction; it shows, furthermore, that iodide of potassium, like chloride of potassium, gives rise to a dilatation of the bloodvessels, which dilatation, even when very large doses are used, is permanent, and at no time followed by contraction. We may, therefore, safely conclude that sodium salts give rise to dilatation followed by contraction of the bloodvessels, and that potassium salts, in large as well as small doses, always cause dilatation of the vessels.

In the next experiment the bromide of potassium was used in the proportion of 1 of the bromide to 3000 cubic centimetres of normal salt solution, or about half the strength of the potassium iodide solution used in previous experiments. The effect on the bloodvessels may be seen to be identical with that produced by the iodide, thus showing that it is not due to the iodine or bromine in combination with potassium, but rather to the potassium part of these salts. This may also be inferred from the fact that the chloride of potassium, too, produces the same effect upon the bloodvessels, namely, it causes their dilatation in small as well as large doses.

In connection with the dilatation of the vessels produced by potassium salts, considerable œdema was invariably noticed; this was absent in experiments with calcium and sodium salts.

Experiment XLIV.—March 26, 1886. Terrapin 650 grms. Inflow canulas in right and left aortic trunks. Outflow canula in sinus. Arterial pressure 18 c. m. Venous pressure 0. Circulating fluids: Normal salt solution, solution of potassium bromide 1 in normal salt solution 3000.

Experiment XLVIII. has been selected from three experiments made with ammonium salts on the bloodvessels, because it represents in a typical manner what took place in all, namely, great dilatation followed by slight contraction; the latter, though rarely observed as coming on during the time the ammonium salt solution is in the bloodvessels, must nevertheless be looked upon as an effect of ammonium salts, for the vessels ultimately recover their normal calibre under the influence of normal salt solution. Hence, the salts of ammonium resemble those of sodium in their effects on the bloodvessels.

EXPERIMENT XLVIII.—March 31, 1886. Terrapin 1210 grms. Inflow canulas in right and left arterial trunks. Outflow canula in sinus. Arterial pressure 12 c.m. Venous pressure 0. The amount of chloride and bromide of ammonium used in this experiment was larger than that used in the remainder of them. The effect, however remained the same. The dilatation produced by ammonium salts, in large or small doses, is prompt and extensive.

With the exception of Ringer's experiments, referred to above, very little indeed is found in literature on the physiological characteristics of calcium salts. The same may be said of the salts of sodium so far as their effect on the circulatory apparatus is concerned.

Potassium salts have been found to cause death by heart-paralysis, being both nerve and muscle poisons. The primary effect of the potassium salts on the circulation is said to be a transient decrease in blood-pressure, together with a slowing of the pulse-rate, but a rise in pressure and an increase in the rate quickly follow. The rate, however, again begins to go down while the pressure may still be on the rise. Finally, large doses have been found to cause immediate and permanent lowering of blood-pressure, as well as slowing of the pulse-rate, which may culminate in diastolic arrest.

Drs. Lauder Brunton and Cash, in their experiments with potassium salts on the bloodvessels, found that potassium chloride gave rise to great contraction, which exceeded even that produced by calcium and strontium salts. This certainly is not the *direct* action of these salts in the case of the terrapin.

The salts of potassium, as is well known, are frequently employed by practitioners in combination with digitalis for the diuretic effects which they produce. If, now, they did produce dilatation of the renal vessels in man as they do in the terrapin, which, I think, is more than probable from the foregoing experiments, their combination with cardiac tonics like, for instance, digitalis, would certainly go far to explain their salutary diuretic effects which they are known to produce in dropsies of all kinds.

According to Funke and Deahne, the salts of ammonium cause temporary contraction of the bloodvessels owing to their stimulating influence upon the vasomotor centres in both brain and spinal cord; the same authors also state that these salts possess a stimulating influence on the inhibitory centre in the brain, thereby causing slowing in the pulse-rate, in larger doses, diastolic cardiac arrest.

In conclusion, we offer the following explanations for the phenomena observed in the foregoing experiments:

1. Calcium salts cause the vessels to contract by virtue of their stimulating influence on the vasomotor ganglia.

2. Sodium and ammonium salts excite, first, the ganglia of the vasodilators; next, those of the vaso-

motors; hence producing at first dilatation, and afterward contraction of the vessels.

3. Potassium salts stimulate the ganglia of the vasodilators only, and consequently produce dilatation; if, however, as was shown in two observations, the dilatation which they produce is followed by contraction, this contraction is so extremely slight that it may practically be neglected; therefore, any stimulating influence on the vasomotor ganglia which they might possess is insignificant when compared with that which they exert over the vasodilators.

THE AMBLYOPIA OF SQUINTING EYES: IS IT A DETERMINING CAUSE, OR A CONSEQUENCE OF THE SQUINT?[1]

BY SAMUEL THEOBALD, M.D.,

SURGEON TO THE BALTIMORE EYE, EAR, AND THROAT CHARITY HOSPITAL.

The question whether the amblyopia which exists in the squinting eye in so large a proportion of cases of concomitant convergent strabismus is a consequence of the squint, or whether it antedates it, and is an important factor in determining its development, is one not of mere theoretical interest, but of practical importance; for upon its solution depends the further question, whether the operative correction of this deformity shall be undertaken at the earliest moment possible after it has become established, or whether it may be postponed, without detriment to the result, to a later period of life. If the views of Schweigger and of Alfred Gräfe, that the amblyopia is a congenital defect, and not a result of the squint, be correct, it is a matter of little moment when the operation shall be undertaken; but, on the other hand, if, as was commonly held before the promulgation of their views, the amblyopia is produced by the squint, in consequence of the habitual negation of the retinal image in the squinting eye, then the question of time is an all-important one, since the success of the operation depends to so great a degree upon the amount of sight retained by the squinting eye at the time of its performance.

The facts which these distinguished authorities have cited, and the arguments which they have advanced, to sustain their views, do not appear to me to be at all convincing, and though the same criticism doubtless applies in a measure to all that can be said in support of the older doctrine, still I cannot but think that the weight of evidence is decidedly in its favor. It has seemed to me, therefore, in view of its practical bearing, that the question which this paper brings up is one which ophthalmologists might discuss with profit.

It is customary to speak of the amblyopia of squint as "*amblyopia exanopsia*," and to place it in the same category with the amblyopia which results, in young persons especially, from the long-continued existence of lenticular or corneal opacity; but this is clearly a mistake, for if the impaired vision be in any sense the result of the squint, it is certainly not due simply to want of exercise of the retina, as is the case with opacity of the media, but to a cerebral process which gives rise to a much more rapid failure of sight, and the outcome of which is better described as a loss of perception in the corresponding cerebral centres, than as an amblyopia of the eye, as Nettleship has suggested.[1] Alfred Gräfe, himself, admits this difference, and yet, realizing, apparently, the unconvincing character of the evidence by which he attempts to sustain his position, he permits himself to use as an argument against the theory that the amblyopia is produced by the squint, the well-known fact that in monocular cataract the exclusion of the retina from participation in vision, even for many years, does not usually (in adult life) result in impairment of its function.

Both Schweigger and Alfred Gräfe[2] reject Müller's theory of congenital retinal identity, and evidently think that by doing so they greatly strengthen their position. I cannot see, however, that such is the case; for, since convergent squint is scarcely ever congenital, and is only rarely seen in early infancy, there is every reason to believe that, whether this fundamental principle of binocular vision—the correspondence of identical retinal points—be an inherited or an acquired law, it is in operation during the pre-squinting years of life; otherwise there would be from the first no stimulus to binocular fixation, and the development of squint in infancy would certainly be the rule, and not the rare exception that it is.

Again, they both refer to the fact that in some cases of non-alternating squint of years' standing the squinting eye retains vision which is nearly, or quite as good as that of the other eye; while in the other cases a high degree of amblyopia is found in squints of very recent development; and this, they think, militates against the view that the squint induces the amblyopia. In reply to this, it may be said that, as a rule, the impairment of vision is certainly greater in squints of long standing than in those of short duration; in the next place, that the non-development of amblyopia in exceptional instances is easily explained without the necessity of abandoning the suppression theory, a marked difference in the refraction of the eyes being competent to produce this result, because the indistinct retinal image which the squinting eye receives under such circumstances causes less confusion, and is, therefore, less apt to be suppressed; and, in the third place, that the development of the amblyopia doubtless begins during the forming stage of the squint, while it is yet unconfirmed, each movement of excessive convergence being accompanied by an effort to get rid of the attendant diplopia, so that it is not at all remarkable that in some instances the impairment of vision should reach a high grade by the time the squint has become fully established; and, furthermore, if this were not the case, who, it may be asked, is in a position to affirm that the alterations of cerebral structure which cause the impairment of vision may not take place within the space of even a few weeks?

Schweigger asks why we usually have diplopia in paralytic squint and not in concomitant squint, and

[1] A paper read before the American Ophthalmological Society, July 22, 1886.

[1] Diseases of the Eye, American edition, p. 238.

[2] See article upon Strabismus, by Alfred Gräfe, in Gräfe and Saemisch's Handbuch, vol. vi., and the chapter upon the same subject in Schweigger's Handbuch der Augenheilkunde.

finds a satisfactory answer in the assumption that in the former retinal identity or coördination has been *acquired;* in the latter it has not been. To my mind, a much more satisfactory answer is, that paralytic squint occurs suddenly, and is usually met with in adults, whereas concomitant squint develops slowly, and almost always commences in childhood. In the former, therefore, we have annoying diplopia, because there has been no incipient stage during which the individual has been learning to suppress the image formed in the squinting eye; in the latter, this faculty, as has been said, is already acquired by the time the squint is fully formed, so that double vision is rarely complained of. Moreover, it is to be remarked that amblyopia from suppression develops more rapidly in children than in adults, and that even where diplopia is present in the early stages of concomitant squint, it is apt to escape our notice, because in children such visual disturbances cause much less annoyance, and are less apt to be complained of, than in adults.

Again, Schweigger urges that the "suppression theory" demands that the image in the squinting eye shall be always and continually suppressed in order to prevent diplopia, but that he has satisfied himself that this is not the case, for he has met with persons in whom it was impossible to produce diplopia, but who, nevertheless, while fixing an object with the good eye in a dark room, saw the image of a candle-flame whenever, by reflection, it was caused to fall upon the yellow spot of the squinting eye. As I understand the suppression theory, it claims that in the beginning there does occur an active exclusion or suppression of the image produced in the squinting eye, but, that in time, in consequence of this process, structural changes take place in the corresponding visual centres, and that, henceforth, we have to do not with an eye which can see, but by an active effort refuses to see, but with one which cannot see though it would; and, furthermore, that when this active process has produced such a degree, and such a kind of amblyopia, as shall do away with the discomforts of double vision, its purpose is accomplished, and it probably ceases to be operative, and as the attainment of this end does not require that there should be loss of light perception in the region of the yellow spot, so great an impairment of vision as this is not to be expected, and, as a matter of fact, is scarcely ever met with. I cannot admit, therefore, that this experiment of Schweigger's has any significance, or that it tends in the smallest degree to disprove the truth of the "suppression theory."

The absence of diplopia in concomitant squint Schweigger explains, as has been mentioned, by assuming that binocular vision (retinal identity) has not been acquired, or, if acquired, has been forgotten; but, as Noyes and others have pointed out, this explanation is not satisfactory, because in many cases in which under ordinary conditions double vision is absent, it can be produced by causing the image of the object looked at to fall upon a different portion of the retina of the squinting eye by means of a prism.

Schweigger makes a seemingly strong point when he states that no one has ever proved that an eye which once saw well has become amblyopic after the occurrence of squint; for, if the "suppression theory" be true, it is exactly this which does happen in most cases of concomitant strabismus. I cannot believe, however, that he has warrant for so sweeping a statement. Possibly he could find no such cases recorded in medical literature, and this is not so remarkable in view of the comparatively small consideration which this subject has received at the hands of modern writers; but that there are scores of cases recorded in the note-books of ophthalmic surgeons in which there has been observed a progressive decline in the vision of squinting eyes, I do not for a moment doubt. Roosa, in his recent paper upon "The results of the operation for convergent squint,"[1] reports one case, at least, of this character. It is to be borne in mind, moreover, that it is always extremely difficult, and often impossible, to ascertain with any degree of accuracy the acuity of vision of very young children, and that when the eye to be tested is a partially amblyopic and squinting one, the difficulties of the task are immensely increased. It is not to be wondered at, then, since the majority of concomitant squints develop, probably, before the sixth year of life, that there should be a paucity of evidence as to the relative acuity of vision of eyes before and after they have learned to squint.

Schweigger's statement that only thirty per cent. of squinting eyes exhibit amblyopia is, I think, scarcely in accordance with the facts; certainly my own experience does not confirm this.[2]

If we turn now to the other aspect of the question, and ask what evidence there is in favor of the view that the amblyopia is produced by the squint, we shall not find the "suppression theory" so devoid of sustaining testimony as Gräfe and Schweigger would have us believe.

In the first place, the character of the amblyopia which we find in squinting eyes is significant. If we ask ourselves what must be the chief sources of annoyance to an individual who has just begun to squint, after having previously enjoyed good binocular vision, we shall find that he has two especial difficulties to contend with—one, the doubling of every object upon which he fixes his attention, in consequence of the false position of the retinal image of this object in the squinting eye; the other, the confusion of vision which results from the images of *different* objects falling upon *corresponding* retinal points, especially in the region of the yellow spots. To get rid of these annoyances he has a twofold task to accomplish—to eliminate the diplopia, he must teach that portion of the retina of the squinting eye that habitually receives the false image of the object which he looks at not to take cognizance of this image; to prevent the image of some object which he is not regarding from being (mentally) superposed and fused with that of the object which

[1] MEDICAL NEWS, Feb. 6, 1886, vol. xlviii., No. 6, pp. 141 et seq.

[2] The sight of the squinting eye is below that of the other in about eighty per cent. of the cases (in which the vision is given) reported by Dr. Roosa in the paper referred to above.

he is regarding, he must ignore all images formed upon the yellow spot of the squinting eye. The successful accomplishment of this task will result in the production of an amblyopia in the squinting eye, which will be regional in character, being most marked in the neighborhood of the macula and over that portion of the retina which receives the false image (so called) of objects regarded by the other eye, and least developed, or altogether absent, in the peripheric parts of the retina which are not concerned in the common visual field. Now, as a matter of fact, does the amblyopia which we find in squinting eyes exhibit these peculiar characteristics, for, if it does, it affords the strongest possible evidence, of itself almost conclusive, that it has been produced by the squint, and that it is not a congenital defect, since such characteristics would be exactly what the one hypothesis would lead us to expect, whereas they would be utterly inexplicable in accordance with the other. I need scarcely say, what every one knows, that its features are, indeed, just such as I have described, central vision and that which corresponds with the part of the retina upon which the false image falls, being especially bad, while peripheric vision, in the direction in which we should expect it to be best, is so good that, as Schweigger, himself, testifies, it helps materially the sight of the individual by enlarging his general field of vision.[1]

Again, the fact that such a monocular amblyopia as we find in squinting eyes, without structural changes distinguishable with the ophthalmoscope, is almost never met with except in strabismic individuals, indicates decidedly that when it occurs under such circumstances it is produced by the squint; for, if it were a congenital defect of such common occurrence as to be a frequent factor in the production of strabismus, it could hardly happen that we could not meet with it quite often in individuals who do not squint. In testing for glasses, especially, it should not be a rare experience to encounter it. That it is, however, an extremely rare occurrence, I think all will agree. Schweigger, it is true, claims to have met with a large number of such cases, but I cannot help thinking that in many of these complicated errors of refraction, which it had not been practicable to work out, were the real cause of the imperfect vision.

The almost immediate restoration of binocular fixation which we frequently see after successful operations for squint, when the amblyopia has not reached too high a grade, is another circumstance which favors the exclusion theory, or, at least, militates strongly against the theory of non-acquisition of retinal identity and the correlated doctrine of congenital amblyopia; for, assuredly, if there had been a failure to establish retinal identity in the first years of life (supposing, for the sake of the argument, that it is an acquired, and not an inherited law), it would be absurd to believe that in later years it might be acquired within the space of a few days.

The theory of congenital amblyopia has doubtless received more general acceptation than would otherwise have been the case, because there are many who think that it affords a more satisfactory explanation of the development of concomitant squint than had been offered previously. While recognizing that a monocular amblyopia would greatly facilitate the development of a squint, if the other conditions favorable to its formation were present, I cannot agree with those who think that Donders's explanation of the origin of convergent squint is insufficient or unsatisfactory. In my opinion, if there be one fact in ophthalmology well established, it is that concomitant convergent strabismus is "chiefly dependent upon hypermetropia."[1] Because hypermetropia is (almost without exception) the essential factor in the production of this variety of squint, it does not follow, as some would have us believe, that all hypermetropic individuals must necessarily be strabismic. That hypermetropia is a far more common condition than convergent squint, Donders fully recognized, and his explanation of this fact —of why some hypermetropes squint, and many others do not—is, to my mind, entirely satisfactory.[2]

In conclusion, I would suggest that, until more convincing evidence is adduced in favor of the congenital amblyopia doctrine than has yet been brought forward by its advocates, it will be judicious for us, in the clinical management of cases of concomitant strabismus, to act upon the older theory—that the squint is the cause of the amblyopia—and, therefore, to give our patients the benefit of the promptest surgical interference.

[1] Schweigger mentions, as a further proof that the squinting eye is used for vision, that strabismic individuals do not have the same difficulty in estimating distance as monoculars; but I am inclined to question the accuracy of this observation; at least, I cannot, in accordance with any theory of binocular perspective with which I am familiar, comprehend how such could be the case.

RADICAL OPERATION FOR STRANGULATED INGUINAL HERNIA; RECOVERY.

By MARY A. SMITH, M.D.,
of Boston.

The literature on this subject, and the various methods employed, have been so fully reviewed in recent numbers of the *British Medical Journal*[1] by Wood, Spanton, Vincent, Jackson, and others, that a repetition here seems hardly necessary.

Since, however, the operation has not yet been fully accepted by the majority of surgeons, it is right that every case operated upon should be fully reported.

The following case is of special interest on account of the complications attending it, prior to the final operation.

Case.—Ellen S., forty-three years old, Irish, widow. Has had two children. Health generally good. About three years ago first noticed a "small lump" in the right groin, but as it gave her no inconvenience, she thought nothing further of it. Last summer she had several "bilious" attacks, at which times she would notice a temporary tenderness in the right groin.

[1] British Medical Journal, 1885.

October 15, 1885. After lifting a hod of coal patient began to vomit. The vomiting and retching lasted twenty-four hours, and the lump in the groin grew much larger and became quite painful. The bowels moved slightly the following day, but there had been no movement since, when seen six days later, nor any further vomiting. Thinks she passed flatus daily. Had eaten nothing for a week except two crackers, with a little tea and water. Continued to work as a cook until October 20th, when pain and weakness obliged her to leave her place. She walked about a mile to a friend's house, and the next day applied at the New England Hospital Dispensary for relief.

Patient looked pale and hollow-eyed, but there was no marked expression of anxiety. Abdomen was somewhat distended, but not sensitive to pressure, except in right inguinal region, where there was a tumor measuring sixteen by twelve centimetres. The tumor was parallel to and just above Poupart's ligament, elevated above the surface and of hard consistence, giving no impulse on coughing and no fluctuation. The skin was red, hot, and œdematous. Patient was sent home and told to go at once to bed. When seen at 4 P.M., the temperature was 103° F., pulse 120, skin clammy. Tumor was less tense, and an impulse on coughing, and gurgling were now quite perceptible. Two enemata brought away a very moderate amount of scybala and considerable flatus. On account of the local inflammation no taxis was employed, but patient was ordered to remain in the recumbent position and was given only scanty liquid diet. An ice bag was applied to the hernia, and a suppository of opium, 0.06 grm. given.

22d. Morning temperature 101°. Pulse 84. Had passed a restless night. Ice bag had been comfortable to her, and tumor was softer, skin less red. During the succeeding week there was a steady improvement in all the symptoms. The daily large enemata usually brought away a small amount of fecal matter, flatus passed freely, temperature fell to 99.8°, pulse to 76. The signs of local inflammation subsided, and the tumor measured eight and one-half by ten and one-half centimetres. The patient's strength was chiefly sustained by means of rectal alimentation.

On October 29th, without any apparent cause, the tumor suddenly increased in size and became painful, the temperature rose to 103°, pulse to 100, and there was some nausea. A large enema of oil, followed by one of water, brought away only a few scybala. On the following day the temperature was 103.8°; pulse 120, irregular. The hernia now measured nineteen by ten centimetres, and was again quite sensitive to touch, and the skin reddened.

31st. Dr. A. T. Cabot saw the patient in consultation, and agreed to the administration of repeated small doses of castor oil. As signs of obscure fluctuation were now present in the tumor, he advised the use of poultices, to be followed as soon as possible by a free incision. An enema now brought away a large dejection, containing the seeds of some grapes which had been eaten three weeks before. The general condition remained unchanged until the following day when it was time to open the abscess. An incision about seven centimetres long was made from a point corresponding to the external ring and extending outward over the tumor, giving exit to about six ounces of fetid pus and some gas. The hernial sac was found highly injected and adherent to the surrounding tissues. A minute perforation allowed the escape of a small amount of thin feces. Irrigation with a warm solution of potassium permanganate was continued until the abscess was thoroughly cleansed, the cavity was then packed with iodoform gauze and covered with salicylated cotton and a bandage. No attempt was made to deal with the intestinal perforation, as being so small it would probably close of itself.

Later it became necessary to make a second incision about two centimetres inside of the anterior superior spine of the ilium, as the upper part of the abscess was not sufficiently drained through the lower opening.

The patient's general condition now quickly improved, the temperature returning to normal.

The abscess was daily irrigated and dressed as before, and there was no escape of gas or feces into the wound after the second day.

On November 6th, a dose of castor oil was followed by a large movement of soft but formed feces, and from this time on the bowels were regulated with pulvis glycyrrh. comp. The appetite now returned and she was allowed to have solid food. The wounds soon granulated up to a level with the surrounding surface, and cicatrization progressed rapidly. The hernia remained as a small protrusion between the two cicatrices.

On November 13th, patient was allowed to sit up in bed for the first time. That night she complained of great pain on the right side of the abdomen. Next day the temperature was 101°, pulse 104, respirations 40, and the pain had become very severe. As the hernial protrusion had now disappeared these symptoms were attributed to the breaking up of some slight adhesions consequent upon the somewhat forcible return of the bowel into the abdominal cavity which probably took place as the result of sitting up. Opium and repeated mustard poultices relieved this condition, and in the course of a week, after the application of a properly fitting truss, the patient was allowed to be about, and soon regained flesh and strength.

December 24th, I was again summoned, and found that Mrs. S., after ironing on the 22d, had begun to vomit and noticed a sharp intermittent pain in the groin. Bowels had last moved on that morning. The retching and green vomiting had continued for thirty-six hours but were now less frequent. The hernia was found protruding below the truss, but was not inflamed or specially sensitive. Copious enemata brought away neither flatus nor feces, and as hot poultices and opium did not relieve the symptoms, an operation was decided upon.

On the morning of the 25th, therefore, the patient being etherized and the usual antiseptic precautions being observed, an incision was made over the tumor and the tissues divided until the sac was reached. This was found to be everywhere adherent to the surrounding structures. Much time was neces-

sarily consumed in careful dissection, at the completion of which reposition was found to be still impossible. The sac was now opened and the intestine thoroughly examined, it was highly injected and distended, but glistening, and after incision of the ring it was returned to the abdominal cavity. The sac was now grasped with clamp-forceps and torsion made after the manner of Ball,[1] resistance being marked after three half turns had been made. The pedicle was ligated with carbolized silk, and the remainder of the sac below the ligature cut off. A continuous suture of strong carbolized catgut was then employed to unite the pillars of the ring, and fix the stump. To secure additional firmness, one silver wire suture was passed through the pillars and pedicle, its ends being twisted and cut rather short. The superficial tissues were then carefully united by eight carbolized silk sutures, the silk of the lower cicatrix, which had been dissected out in freeing the sac, being utilized for the insertion of a drainage tube. A strip of iodoform gauze was placed over the line of sutures, and covered in by rubber adhesive plaster, and an antiseptic dressing.

Patient recovered quickly from ether, and had no nausea.

Drainage tube was removed on the third day, and the stitches on the seventh. Union by first intention took place throughout the wound with the exception of a small place where the drainage tube was inserted, and this soon granulated out.

Castor oil was administered on the fourth day, and was followed by a free evacuation.

Convalescence was soon established, the patient sitting up on the fourteenth day.

March 16, 1886. The patient is now working as cook and laundress, and shows no signs of any return of the hernia.

MEDICAL PROGRESS.

BISMUTH SALICYLATE. — In view of the satisfactory results obtained by Solger and Vulpian from the use of this salt, and the diverse experience of others, LANGGARD calls attention to the fact that the salt is found commercially in two forms, one of which is medicinally inefficacious. The two salts are the acid salicylate and the subsalicylate of bismuth. The former contains forty-one per cent., the latter twenty-four per cent. of salicylic acid. The basic salt (the subsalicylate) is the useful form, and is prepared by washing the commercial salt with distilled water until the wash water gives no violet reaction with ferric chloride.—*Deutsche med. Wochenschr.*, July 3, 1886.

WINTER INDIGESTION.—In an opening address delivered before the Section of Medicine at the Brighton meeting of the British Medical Association, DR. W. H. BROADBENT spoke as follows on the topic above indicated:

As cold and damp weather sets in, there are many persons who begin to suffer from pain after eating, and flatulence; or these symptoms may not set in till later in the winter, when the cold and short days have reduced the vital powers. Very frequently the connection between the indigestion and the season of the year is not recognized, and the subjects of it simply look upon themselves as liable to dyspepsia, which they associate with certain articles of diet, instead of with the winter, or attribute it to want of exercise and fresh air. As is well known, however, cold, and especially cold with damp, will inhibit digestion, sometimes so completely that a hearty meal, eaten with avidity after a cold drive, will be vomited almost unchanged hours afterward, but this takes place more frequently in a minor degree, sufficiently to give rise to discomfort, and a sense of distention, or the cold will inhibit the hepatic functions, and cause constipation.

Now in all such cases it is not the food which disagrees with the stomach, but the stomach which disagrees with the food; and the appropriate treatment is not levelling down the nourishment to the digestive capacity of the stomach, but the bringing up of the functional energy of the stomach to the requirements of digestion, by extra food of a stimulating character, such as beef-tea, or an egg-flip, between meals, by stimulants at meals, and by tonics. So with regard to winter indigestion; winter is not the time for cutting off food, when it is required in larger amount to neutralize the influence of external cold. What is wanted is protection from the depressing influence of cold, or the means of neutralizing it.

It is quite true that most people eat far too much, and, again, that with regard to the stomach, as well as to all other organs and parts of the body, the principle of functional rest is of primary importance in dealing with disease; and restriction of food, and even temporary starvation is often necessary; but we must distinguish, and not starve those who are suffering from inadequate nourishment, or employ treatment for catarrh, or ulcer, or organic disease, when nothing of the kind is present. —*British Medical Journal*, August 14, 1886.

THE RELATIONSHIP OF BODILY AND MENTAL PAIN. —In the opening address before the Section of Psychology at the August meeting of the British Medical Association, DR. T. S. CLOUSTON presented the following suggestive account of the relation existing between neuralgia and melancholia:

In hypochondriasis we have a disease where there is neither acute bodily nor intense mental pain, but a combination of both in a modified and mixed-up way. No one who has seen a strong intellectual man pass through an attack of hypochondriasis, or of melancholia of the hypochondriacal type, and seen him recover again, can doubt that these were real diseases, caused by disordered energizing of the brain-cortex, however much the symptoms during the attack seemed mere "imaginations," and the strange conduct appeared controllable by the will, if the patient had chosen to exercise it. But there are few mental diseases where a man's normal volition, his feelings, his habits, and his power of working, will be more inhibited than in this. The pains and discomforts, the imaginary disorders of function, and the general sense of organic ill-being of the hypochondriac, I look on as resulting from an equal disturbance of the mental and sensory portions of the brain-cortex; just as in ordinary melancholia there is an unequal disturbance, the mental portions being most

[1] British Medical Journal, Sept. 6, 1884.

affected. No doubt, the areas that control and specially represent the organic viscera, and their special nerve-ganglia are specially disturbed in function in these cases.

From the prophylactic point of view, the general association of melancholia with sensory disturbances has a special value. Some pain or sensory perversion usually preceding the mental disease, the physician can take early measures of prevention. How many attacks of melancholia could be averted if proper measures were only taken in time!

It appears to Dr. Clouston that physicians in general practice frequently do not realize the significance of slight mental depression, accompanying or following neuralgia or sensory perversions, and that psychiatrists often do not sufficiently think of the sensory symptoms in the study and treatment of melancholia. The borderland between neuralgia and melancholia he looks on as a very slight one indeed. They are both manifestations of one type of the neurotic diathesis. The seat of both is in the brain-cortex, and in the same part of the cortex, though not in the same cells. The actual cortical conditions under which the mental and the bodily pains arise would appear to be the same; therefore, it seems clear that they should not be studied or treated apart from each other.—*British Medical Journal*, August 14, 1886.

Essence of Turpentine as a Styptic.—Bodier states that he has frequently arrested serious epistaxis by the use of tampons dipped in essence of turpentine, introduced simply into the nostrils. The essence is partially vaporized by the body temperature, and in this state reaches the most unaccessible portions of the nasal cavities. He has also arrested, by the internal administration of the same agent, intestinal hemorrhages, and has found it of great service in checking bleeding from the gums. In his experience this drug is a more efficient styptic than the perchloride of iron.—*Journal de Médecine de Paris*, August 1, 1886.

Chloride of Sodium in Bright's Disease.—Dr. Allard Memminger, of Charleston, S. C., highly lauds this use of the drug in the *New York Med. Journ.*, July 31. He has tried it, so far, in only four cases, but his observations are of value, because it alone was used, to the exclusion of all other drugs. At first he orders ten grain doses of the chloride, contained in gelatine capsules, three times a day, and, if the state of the case allows, by preference one hour after or before meals. He generally reverses each day the order of giving; thus, if one day the capsules are given before meals, the next they are prescribed after. If the patient complains of no nausea, he allows him to go about; but at the slightest intimation of a sick stomach, he orders him immediately to assume the recumbent posture, and there remain for an hour or so, after which this temporary ill-feeling always subsides. The second day of treatment he increases the dose to two capsules three times a day, and every other day he increases by one capsule until the patient is taking five capsules three times a day. About this time the good effects of the treatment will be apparent, not only from the improved subjective and objective symptoms of the patient, but from the improved condition of his urine. Albumen will, of course, at this period still be found in abundance—that is, if the case is at all a grave one; even here, however, if a gravimetric examination be instituted a decided improvement, not so much in the absolute as in the relative decrease in albumen, is noted.

At this juncture he orders the chloride to be diminished in quantity, and he has so far found that after the system has thus been brought fully under its influence, it requires but two capsules, three times a day, to keep up the desired effect. If at this stage of the case there is any decided nausea or disinclination to take the medicine, he stops the treatment, and in the interval gives one or two alterative pills, after which he proceeds again to a resumption of the chloride. Should albumen again increase in the urine, urea and chlorides diminishing, he immediately resorts to large doses, thus bringing the patient once more under the influence of the chloride, after which it is again reduced.

The effects of this treatment are most marked. Headache, œdema, low spirits, general weakness, and anæmia, give way to just a reverse order of things, and the patient, who a few days before was most gloomy and desponding, is now full of life and hope.

Thus has it appeared to him in each of his four cases, and, if he has been led to express views that to many appear extreme, it is because his convictions are based upon clinical observations which, up to this time, he has never had the pleasure of recording with any other form of treatment. He would, therefore, urge a thorough trial of this therapeutical agent by the profession, on the following grounds:

1. It is harmless if properly administered.

2. Its effects are comparatively uniform, provided it is given for a sufficient time. That he has so far used it only in chronic cases of no long standing does not, in his opinion, militate against its beneficial effects; for, even should it not be found a cure for Bright's disease, may it not become an important article in our medical armamentarium — indeed, if only an ameliorator of man's sufferings and a prolonger of his life?

3. It may be employed as an adjunct to all recognized methods of treatment without detriment to the patient.

A Research on the Reality of Reichenbach's Flames.—Prof. Wm. H. Pickering, of the Massachusetts Institute of Technology, has presented the following report to the American Society for Psychical Research, which appears in its *Proceedings* for July, 1886.

In the experiment described below, an electro-magnet was employed, with coils measuring eight inches long by five in diameter, and with the pole pieces about half an inch apart. It was placed in a dark room, the walls, floor, and ceiling of which were painted black, and all the cracks covered with rubber cloth, so that not a ray of light entered. A powerful current was passed through the coils of the magnet from a two-light Brush dynamo. After sitting for half an hour in absolute darkness, a faint greenish light was seen in front of the observer's eyes. But it was found that this was quite independent of the magnet, and that it did not disappear when a screen was placed between the magnet and his eyes. When the current through the coils was made or broken by an assistant, no perceptible effect was produced. A person totally unacquainted with physiological optics might readily mistake the subjective phenomenon for an objective reality; but the simplest tests, properly

applied, would distinguish between the two. There was a very powerful permanent horseshoe magnet in the dark room, but no glow could be seen in connection with it.

In the above described experiment, as I was the only percipient tested, it should be mentioned that my eyesight is unusually good in the dark, as is shown by the fact that I can see eleven Pleiades with the naked eye, where many people see only six. If the flames, therefore, were visible to all persons with more or less distinctness, and were not exclusively a nervous phenomenon, I certainly should have made a good subject. As, however, no flames were seen, and the apparatus employed was fully as powerful, if not more so, than that used by the English society, the experiment seems to confirm the view that, even under the most favorable conditions, the flames, if they exist at all, produce no effect whatever on the senses of a normally constituted person.

The Pathological Histology of Compensatory Hypertrophy of the Kidneys.—Lorenz has made direct micrometric measurements of the histological elements of the kidneys in seven cases of experimentally induced compensatory renal hypertrophy, with the following results:

The hypertrophy consists chiefly in an increase of the cortical substance of the kidney, and, to a much less degree, of that of the parenchyma. The cortical increase is caused in young animals by both hypertrophy and hyperplasia (numerical hypertrophy), while in older subjects the increase in size is due to simple hypertrophy of the elements.

The convoluted tubules were always enlarged, and the epithelium is thicker and wider than in normal subjects. The relatively slight increase of the parenchyma is conditioned by enlargement of the lumina of the straight tubules without increase in the size of the lung epithelium. No hypertrophy of the connective tissue or capillaries was found.—*Centralbl. f. d. klin. Med.*, July 31, 1886.

The Treatment of Rabies with Hoang-nan.—According to the *Gazette Médicale de Nantes*, twenty-four cases of rabies have been treated with hoang-nan by Dr. Barthelmy and several other medical men of that city or of the department. The first case so treated was in the month of March, 1882, the last in April, 1885. Ten times, at least, the bites, which were most frequently multiple, were situated on the hands, once on the hands and on the face. In the majority of cases cauterization was completely omitted, or practised several hours or even several days after, with not very active agents, such as liquid ammonia, or a solution of carbolic acid. Two of the patients, who were closely observed by Dr. Barthelmy—viz., a man of thirty and a lad of sixteen—presented symptoms of rabic mania: persistent insomnia, anxiety, nocturnal agitation, the desire to run, hallucinations, barking, etc. However, none of these persons felt hydrophobia, nor have any of them, to this date, succumbed. The duration of this preventive treatment was, on an average, twelve days. The total dose of the powder of hoang-nan ingested during this time varied in adults from six to eight grammes. It was scarcely necessary to go beyond one gramme per day to obtain the physiological effects of the medicine—exaggeration of the reflexes, cramps, rigidity, slight trismus. The maximum dose was arrived at progressively, and in some cases the treatment was terminated by gradually decreasing doses. From the above cases the author deduces either that rabies is communicated much more rarely to the human species than is generally admitted, or that the hoang-nan, administered progressively to the physiological effects *during the period of incubation*, sufficiently and efficaciously modifies the nervous system and the entire economy to prevent the evolution of the rabic virus.

Safety of Cocaine in Cataract Extractions.—Dr. G. E. Frothingham presents, in the *Journal of the American Medical Association* for August 21, 1886, an account of thirty-nine cases of cataract extraction in which cocaine was employed, and deduces from his experience the following conclusions:

1. Cocaine relieves the operator from the embarrassments during the operation for cataract that arise from vomiting, also from the agitation of his patient which results from excessive bronchial secretion or stertorous breathing. These are often very troublesome when ether or chloroform is used.

2. The danger to the result which often arises from nausea and vomiting after the extraction, when other anæsthetics are employed, is very surely avoided when cocaine is selected as the anæsthetic agent and is properly used.

3. The danger arising from the depressing effect of cocaine upon the nutrition of the cornea is no greater than in cases where ether or chloroform is used. The depression of the circulation which often arises from either of them, may affect very injuriously the corneal nutrition.

4. The disturbance of the circulation of the interior of the eye, and consequent danger of panophthalmitis from this cause, is probably less in using cocaine for this operation than in resorting to general anæsthesia.

5. The danger of sepsis and consequent panophthalmitis from the use of cocaine may be avoided by using only fresh solutions.

Measurement of Lower Limbs.—Prof. C. L. Ford, of the L. I. College Hospital, called attention, in 1862, to the fact that the lower limbs were not always of the same length in the human subject. This statement induced anatomists and surgeons to make an extended series of measurements, and the results confirmed the opinion expressed by Professor Ford. Garson, in the *Journal of Anatomy and Physiology*, sums up these observations. In seventy skeletons examined, he found the lower limbs equal in but seven. His measurements show that in 54.3 per cent. the left limb was longer than the right; in 58.5 per cent. the left thigh-bone was longer than the right. The right tibia was longer than the left in 41.4 per cent., and the two bones were found equal in but 10 per cent. The difference in the length of the lower limbs varies from one-eighth of an inch to one inch and five-eighths, without any deformity being recognizable. In a series of measurements of the collar bones, only six, in twenty-two cases examined, were found to be equal.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 4, 1886.

THE MALARIAL GERM OF LAVERAN.

NEARLY six years ago LAVERAN, a French Army Surgeon, announced to the Paris Academy of Medicine that he had discovered, in the blood of patients affected with malaria, an organism which was possibly the germ of the disease. His observations, made chiefly in Algeria, have been extensive, embracing many hundreds of cases, and the full results of his studies have been given to the profession in a work entitled *Traité des Fièvres Palustres*.

At the time of the publication of his early papers, the attention of those interested in malaria was directed to the bacillus malariæ of Klebs and Tommasi-Crudelli, an *ignis fatuus*, which led many astray; and, although Richard in 1882 reported observations confirmatory of those of Laveran, it has only been within the past six months that the papers of MARCHIAFAVA and CELLI and of TOMMASI-CRUDELLI have aroused a fresh interest on the subject. In this country COUNCILMAN has given the question careful study, and, in a paper read at a recent meeting of the Association of American Physicians, states that he has been able to verify the observations of Laveran. STERNBERG was shown the organisms by Celli, in Italy, and has also had an opportunity of seeing them in the blood of a patient in Baltimore. We have been able, without any difficulty, to find these bodies in cases of acute malaria, and the fact of their presence in the blood in this state can be readily demonstrated. The questions of their true nature, and of their relation to the disease, remain under consideration.

The parasite presents several different forms, corresponding possibly to stages in its development. It occurs most frequently within the red corpuscle, but is also met with in the plasma. Inside of the corpuscle the organism presents the appearance of a rounded or irregular-shaped body, either hyaline or else deeply pigmented. The latter form is most abundant, and the dark granules inside the corpuscles serve as indicators or guides for their detection. On watching these bodies remarkable alterations in outline are seen, which seem unquestionably to be vital—*i. e.*, amœboid. All observers lay stress upon this phenomenon as a distinctive feature. The pigment granules also display Brownian movements.

Free in the plasma small amœboid bodies occur, similar, apparently, to those within the corpuscles. Another phase of existence is presented by a ciliated organism, which appears to be the pigmented body above described, provided with vibratile lashes. This form is much less common, having been found in only 92 of 432 cases by Laveran, and in 4 of 24 cases by Marchiafava and Celli. We have also seen a body of this kind which conformed to the description given by the French and Italian observers. In dry preparations of the blood, the bodies in the interior of the corpuscles stain readily with the aniline dyes.

Granting the truth of these observations, we have evidently here an organism of a character very different from that of those associated with the specific fevers. The description is that of a flagellate infusorian, with an amœboid phase of development, and should this body turn out to be the veritable germ of malaria, it will be the first instance of a widespread endemic affection associated with protozoan forms.

Marchiafava and Celli have proposed for this organism the name *plasmodium malaria*.

We hesitate, however, to accept, without further evidence, its etiological connection with the disease. While apparently a constant feature in the blood of acute cases, they are sometimes in such scanty numbers that it may require several hours' searching to find them. On the other hand, Councilman has shown that in pernicious cases the blood literally swarms with these bodies. Marchiafava and Celli claim to have produced, in five cases, typical attacks of ague by the injection of blood of a malarial patient, and they have found the pigmented bodies in the subjects of the experiment. Cultures have failed, and, until we have more positive knowledge of the life history of these organisms, we cannot feel sure that we have here the true germ of the disease. Von Sehlen has published in Virchow's *Archiv* for May, 1886, an elaborate criticism of these views, and holds that the evidence of the dependence of malaria upon a micrococcus, which he had described, is a much more likely view. He doubts the parasitic nature of the pigmented bodies, and thinks

they result from a transformation of the hæmoglobin under the influence of the micrococci.

In view of the lamentable mistakes which have been made in this disease by so many good observers, the most rigid scrutiny should be exercised in accepting evidence, and it is to be hoped that those who have the opportunities and the necessary technical skill will soon place us in a position to give an opinion upon the *plasmodium malaria* as positive, one way or the other, as we now can upon the *bacillus malariæ*.

THE PASTEUR METHOD OF TREATING HYDROPHOBIA.

In The Medical News for June 12, 1886, we called attention to the opinions of Frisch, of Vienna, in regard to the method of Pasteur for the prevention of the outbreak of hydrophobia. We thought it important to do this because these opinions had been entirely misunderstood, or misrepresented, by a certain number of medical journals, which reported Frisch as strongly endorsing Pasteur's method. Very recently we have noticed a repetition of this misunderstanding of what Frisch has really said, and believes, and, curiously enough, it appears at the very time that Frisch is making two new communications upon the subject, which are to be found in the *Wiener med. Presse*, of August 1 and 8, 1886. In the first, Frisch refers to the previous communication, in which he pointed out the want of analogy between the experiments of Pasteur and his application of preventive inoculations to human beings. He also recalls his suggestion that the true test of Pasteur's theories would be to inoculate a number of animals with his specific virus by trephining, and then to apply his protective method. This suggestion was made in the greatest friendliness, on the 29th of April, but we have not as yet heard that it has been adopted by Pasteur. Frisch, however, has not waited for Pasteur to apply this test to his theory. He has applied it himself. The result is what would have been anticipated by those who have regarded Pasteur's theory as illogical and erroneous.

Frisch inoculated sixteen rabbits by trephining, with a virus made by rubbing up in sterilized *bouillon* a piece of the spinal cord of a rabbit dying after an incubation of sixteen days, after inoculation with virus derived from a rabid dog, and conveyed through two generations of rabbits. This is a typical virus, according to Pasteur. In fifteen of these rabbits Frisch made preventive inoculations with what Pasteur calls the "fixed virus"—the spinal cord of rabbits dying after an incubation of seven days, after inoculation with virus derived from rabbits which Pasteur himself had inoculated and given to Frisch. In the case of the first rabbit, the preventive inoculations were begun twenty four hours after the trephining, and, in the case of each successive animal, after an additional interval of twenty-four hours more. This was done in order to determine how long before the outbreak of the expected rabies preventive inoculation would be efficient. One rabbit was not subjected to the preventive inoculation, and served as a control experiment. This animal fell sick on the 18th day, and died on the 21st day after being trephined. Of the animals which were subjected to the preventive inoculations, every one, likewise, died with the customary symptoms of Pasteur's rabies after the usual period of incubation. All but two presented the symptoms of rabies between the 13th and the 19th day, and died between the 14th and the 21st day. Two lived to the 28th and 33d day. The thirteenth, fourteenth, and fifteenth rabbits presented symptoms of rabies before the preventive inoculations were begun. In a second series of sixteen experiments, Frisch attempted to shorten the time required for the eleven preventive inoculations of Pasteur by omitting some of them, so as to render the animals sooner fit for the stronger virus. All but one of these animals died, like those of the first series, of rabies. The escape of this single animal out of thirty-two experimented upon, Frisch thinks, is to be accounted for on the supposition that, in its case, the virus with which it was inoculated did not "take."

To test the specific character of the disease of which the thirty-one died, Frisch inoculated portions of the spinal cord taken from them upon other rabbits, all of which died, with the usual symptoms, between the 9th and 14th days. According to Pasteur's theory, this amounts to a demonstration.

Frisch next tested the preventive inoculations on dogs. He inoculated five dogs with virus derived from a rabid dog, and carried through four generations of cultivation in rabbits, the last of which died after a period of incubation of fourteen days. Three of these dogs were subjected to preventive inoculations, two were not. The latter became rabid on the 12th and 13th days; the first died in thirty-six hours, the second was killed in forty-eight hours. Of the three protected dogs, two died of pronounced furious rabies on the 15th and 18th day after inoculation. The third dog was apparently well on the 23d day after inoculation.

Frisch also inoculated six rabbits, by hypodermatic injection, with portions of the cervical spinal cord of a dog with ordinary rabies—what Pasteur calls "rage des rues." Three of these rabbits he subjected to the preventive inoculations, three were left unprotected, and all alike remained perfectly well when he made his report, four weeks after their inoculation.

The conclusion Frisch arrives at from these experi-

ments, is that neither in rabbits nor in dogs is it possible to prevent the outbreak of rabies by means of Pasteur's preventive inoculations, if infection has taken place. The peculiar force of Frisch's experiments lies in the fact that they were undertaken for the express purpose of testing Pasteur's theory by one who is his friend, and who had every reason to hope for a different result from that which he obtained.

It is a curious coincidence, that the President of the Local Government Board stated, in Parliament, on August 26th, that the Commission appointed by the British Government to examine into Pasteur's method were fully satisfied that his treatment for hydrophobia was effective. Until we have the grounds for this opinion, it will be impossible to estimate properly its value, although it must prove encouraging to those who still hope that Pasteur's method will prove to be trustworthy.

In the discussion of Pasteur's recent announcements in regard to the nature and treatment of rabies and hydrophobia, there has been a good deal of feeling shown by Pasteur's defenders and by his opponents. With this feeling we have nothing to do; but, looking at the matter in as judicial a frame of mind as is possible under the circumstances, we cannot but feel that the true state of the discussion may be still summarized in the expression used in these columns last June, when we stated that there is as yet no good evidence that the application of the theory of Pasteur has rescued a single patient who without his intervention would have had hydrophobia.

DILATATION OF STRICTURE OF THE ŒSOPHAGUS AFTER GASTROSTOMY.

THE advantages to be derived from an operation by which food can be introduced into the stomach notwithstanding the presence of a stricture of the œsophagus are well recognized, but the value of the operation of gastrostomy will be greatly enhanced if it can be made the means of curing the stricture itself. Several surgeons have made attempts in this direction. Bergmann and Schattauer, for example, have succeeded in passing bougies through a stricture of the œsophagus from below upward; and WEINLECHNER has passed a delicate sound down through the stricture, and out of the opening in the stomach. Another method of utilizing the gastric fistula consists in passing a slender sound from above the stricture, and out of the artificial opening, then attaching a thread to its upper end and drawing after it larger instruments. This method has been employed by Weinlechner, who used the thread to draw into the stricture pieces of drainage tube, which were allowed to remain in position, in the hope that their elasticity would have the effect of steadily dilating the stricture. In the only case in which he did this the patient died of tuberculosis. A similar procedure is described by VON HACKER in a monograph on operations upon the stomach, published this year. His plan was to attach a drainage tube to a slender sound, and draw it through the stricture in a state of extension. He believed that when the tube was no longer stretched it would regain its previous calibre, and produce active dilatation of the stricture. It does not appear that this plan has ever been put into practice; and it is easy to see certain objections to it, as, for example, that the elastic tube might break; that its end might double over at the point at which the thread was tied and injure the diseased part of the œsophagus; that it might, if small, become wrinkled and not expand at all; or, if thick, that it might become intolerable or dangerous to the patient.

An apparently much better method has recently been proposed and used by MADYL, who describes it in the *Allgemeiner Wiener med. Zeitung*, for June 15, 1886, as follows: He introduced through the cicatricial stricture of a patient, twenty-two years old, a fine bougie, No. 5; he then anæsthetized the patient, passed a sound into the opening in the stomach, which he had dilated with a sponge tent, found the end of the bougie, seized it with urethral forceps, and drew it down till it protruded from the stomach. He next pierced the upper end of the bougie, which protruded from the mouth, with an awl and attached to it a strong double silk thread twice as long as the bougie. He now drew down the bougie through the œsophagus and stomach and pulled the thread after it. He then tied the upper end of the thread into the lower end of a large bougie, No. 10, drew this carefully down through the stricture, and left it in place for twenty-four hours. In order to make the treatment as little irritating as possible, Maydl took the precaution to draw the upper end of the bougie down into the œsophagus, after having attached a thread to it, which was secured to a pledget of gauze retained in the nose. He also secured the patient's hands, so that he could not pull the bougie out when it proved irritating. In twenty-four hours the bougie was withdrawn through the stomach and with it the thread was drawn down, and was then left in place for three days. At the end of this time a larger bougie was drawn down by means of the thread, and was left in place for twelve hours. The subsequent steps consisted in introducing a larger bougie every second day, diminishing the time which it was allowed to remain, and leaving the thread in during the intervals. In order to reduce to a minimum the irritation of the manipulations, a small quantity of a five per cent. solution of cocaine was swallowed. Maydl found it best to introduce the thread through the nose, and not by

the mouth, because it is less irritating in the former situation.

The obvious advantages of this ingenious method are that when once the opening of the stricture is found, the way to it is never lost. This is sometimes no small matter, as it is common to find an enlargement of the œsophagus above the seat of a stricture, and a small bougie may easily miss the central channel. The retention of the bougie in the stricture is likely to have a similar effect to that of a *sonde à demeure* in the urethra, and to lead to a more speedy resolution of a stricture than could be hoped for from the repeated passage of such instruments.

The tediousness of the old method of dilatation need not be described here. It is more important to note that in a few days Maydl's patient reached a point where he was able for the first time in a year to eat a piece of meat in the natural way, and that the operator hoped in two weeks to be able to pass through his stricture the largest bougies. This success is encouraging, and on its face the method seems well adapted to the treatment of cicatricial strictures of the œsophagus. Of course, much is not to be expected from it in case of malignant strictures.

SOCIETY PROCEEDINGS.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

Tenth Annual Session, held at Greenwich, Conn., August 25, 26, and 27, 1886.

WEDNESDAY, AUGUST 25.—FIRST DAY.

MORNING SESSION.

THE PRESIDENT, DR. EDWARD WIGGLESWORTH, of Boston, called the meeting to order, and opened the session with the following

PRESIDENTIAL ADDRESS.

Gentlemen: Just ten years ago, at Philadelphia, I had the honor of calling to order the first public meeting for the organization of this Association. Our specialty for the first time received national acknowledgment. Our guerilla warfare was over, and our subsequent record has been one of unbroken, successive victories over bigotry, error, and ignorance.

But the day of paladins is past and our ranks will admit more recruits. There are still remaining opportunities for more extended instruction of students in medical schools, while the lack of hospital facilities for the proper clinical treatment of diseases of the skin, is a standing shame and disgrace to our municipal authorities, our hospital boards, and to the medical profession itself. "As now arranged nearly everywhere amongst us, these institutions refuse, to a large class of sick persons, the benefits of hospital residence either wholly, or offer them, if received, not, we may fairly say, the best medical skill it is in their power to procure." Some progress has, however, been made. New York has now a special hospital for skin diseases, besides two wards in the Charity Hospital, and Philadelphia has special clinics with beds at three different institutions.

That the workers are ready as soon as they shall have opportunity is evident. Ten years ago our officially recognized representatives were, four professors, five clinical professors, one instructor, and six lecturers; total sixteen. To-day we number seventeen professors, eleven clinical professors, six instructors, and sixteen lecturers; total fifty. Nor do I include genito-urinary surgery, which I regard as a distinct specialty from that of dermatology, which, of course, includes syphilis.

About twice as many cases of diseases of the skin are now annually treated by specialists as there were ten years ago. The contributors to American dermatological literature during the past decade include the best treatises, handbooks, and atlases, the only periodicals, and some of the best monographs of the time, in the English language. Our sole local organization, the New York Dermatological Society, is as active as ever, and the good work which it has already done is constantly increasing.

Two honorary and three active members of our original Association have passed away since its organization. Twelve active members, all living, have been added to its ranks. So much for our material progress and present prosperity.

Other objects of the foundation of our Association have been by no means neglected during the past ten years. There exists to-day a harmony and good feeling amongst us which, but for the personal acquaintanceship resulting from the formation of this Association, never would have existed. We have come into better accord as to the "nature and treatment of skin diseases." Our increased membership proves that our Association is "held as a place of aspiration;" and it has consistently required "independent work in our department" as the essential preliminary step toward the acquisition of such membership. The systematic work of our standing committee upon statistics has already furnished valuable data for comparison, as well as a series of excellent reports upon "leprosy in America." Concerted official effort has done much and will do more to repress the rank luxuriance of growth of dermatological nomenclature and to furnish a "uniform and simple system."

While much has been accomplished, much still remains to be done. The idea of specialism, already rooted, is to be nurtured and trained in the minds of the profession and of the public, and the practical development socially of our specialty itself is to be elaborated in many minor details. The pioneer must no longer prove a martyr. A knowledge of the weaker side of human nature, useful for selfish financial ends, must no longer be allowed to usurp the province of exact scientific acquaintance with disease, inuring to the benefit of our race. The "elaborate division of labor" is "as useful and successful in a learned profession as it is in the mechanical arts," for it is merely a relative question of height of standard. Specialism substitutes quality for quantity, which substitution is the essential characteristic of the civilized man as distinguished from the savage, while the rapidity of such substitution gauges the progress of civilization itself. Medicine is merely that complex whole which results from the combination of all its component parts, and

their individual advancement is the criterion of its own progress.

Science is only exact knowledge. Medicine is that knowledge specially directed to the physical welfare of mankind, and specialism is only that further subdivision rendered necessary by the very various parts composing the individual, and possible by the extension of our opportunities for studying these parts due to increase of mechanical means for enlargement of the fields of our hitherto unaided senses. No one can to-day "take all knowledge to be his province." Science does not culminate in a Jack-at-all-trades, least of all in one whose conscience has become anæsthetized by custom, who confounds his own limitations with the "limitations of human understanding," and his own ignorance with "the immaturity of medical therapeutics." The specialist builds his own boundary wall and cannot, if he would, poach upon the preserves of others. He "distinguishes what he can do from what he cannot," thus filling the old definition of the best physician. He cannot maltreat a patient, and when compelled to confess ignorance and seek superior wisdom, charge the wronged sufferer another and still higher fee for a "consultation," which is in reality a confession. It has been sarcastically called "the sole duty nowadays of the family doctor is to decide what specialist shall be summoned." It certainly is his duty, and a very important one as a man of honor, to decide whether any one, and if so, who can probably accomplish that wherein he admits that he himself has failed. Unfortunately, many know so little that they are even ignorant of how much is known by others; but in many respects the specialist has already raised the average standard of requirement for general practice to such an extent that much of the old routine practice of physicians who treated their patients for the very diseases for which they referred members of their own families to the specialist, has now become punishable malpraxis. But the general practitioner has his revenge in opposing as unnecessary the hospital appointment, and even the private practice of the very specialist to whom he himself flees as "a help in time of trouble."

We are told that "the human body is made up of parts and functions so thoroughly interdependent, that it cannot be parcelled out into defined and isolated regions." It can and it can not. What scientist divides a country into square miles and attempts to become thoroughly conversant with every atom existing in each of those miles? The special divisions of study are rather the flora, the fauna, the geological strata, etc. though all these may pervade identically every mile of the region. If regional surgery is possible, then specialties are certainly not contraindicated. We hear of "appalling pathological conglomerates" due to lack of proper "general medical treatment." Not only "conglomerates," but often single lesions are very variously diagnosticated by different general physicians, and the "conglomerates" are usually merely the aggregated effects of original causes which might have been obviated by proper investigation in due season, on the part of suitable specialists.

The aforetime "consulting physician" meant one who, in addition to his general acquirements, knows more about some particular thing than any one else. We may be sure that his general acquirements had to pay the penalty. To-day, we honestly admit this, and renouncing the practice obtainable by general acquirements, keep to that particular thing of which we know more than others. No one has mental ability enough at the present time to add to the greatly extended knowledge necessary to the general physician, the intensified fundamental acquaintance with detail needed by the specialist. Life is too short for the ablest intelligence to exhaust even any one specialty. The physician may, like Newton, "think the thoughts of God after him," but the thoughts of the infinite upon the smallest molecule of matter, call for more than the limits of a finite existence. The true consulting physician of to-day is the specialist, and he should therefore receive this title at the hospitals with which he is connected, while those ex-physicians, called consulting, but never consulted, should receive their true and proper title of Emeriti.

But enough of the "idea of specialism." The public will, in time, appreciate the absurdity of being content with inferior results in one branch of medicine, because, forsooth, there are so many others in which their medical adviser is equally or more at home. It will reason rather that he who "insists upon doing the work of ten men, manifests a quality of mind which we can only call arrogance, and which challenges for his work severe criticism." Versatility will not atone for crude and imperfect work, any more than will lack of time, hurry of life, keenness of competition, or financial necessity, and it is merely brazen self-assertion which delights "not so much in doing the thing well as in showing how well he can do it."

Believing in the ultimate achievement of all possibilities and in the progress of truth, I have no doubt as to the future of specialism if we are honest and earnest. Not infinite omniscience, but infinite morality is the duty of the specialist, and this conscientiously carried out, will blunt the sharpest dart of the hostile general practitioner. While visions of what yet remains to be accomplished might well lead us almost to despair, a mere glance at the generally prevailing ignorance on the part of both physicians and their patients, shows conclusively that we and our work are imperatively demanded.

Dr. Wigglesworth next considered in detail the duties, in the future, of members of the Association as to the establishment of special skin wards in all general hospitals; as to a revision of the existing nomenclature and classification of skin diseases; as to improvements in the annual volume of *Transactions;* the use of the metric or international decimal system; more extended statistics; the establishment of a permanent committee upon new remedies; the question of fees and the remuneration of physicians by others of the same profession; the desirability of a (proposed) "consistent schematic plan for the report of cases," always accompanied by a summary; and the duties of specialists as to instruction. He mentioned the establishment in New York of a society for the prevention of contagious diseases. Attention was also called to the proposed union of all the special medical associations of America into a general congress.

Dr. E. B. Bronson, of New York, presented an essay

ON ERYTHANTHEMA SYPHILITICUM.

He called attention to certain cutaneous eruptions

of an erythematoid character occurring in connection with syphilis, and desired so far as possible to determine their etiology. A case was reported of a syphilitic patient who developed a peculiar eruption upon the head, hands, and feet. Although the eruption presented no pronounced syphilitic characteristics, it was regarded as due to syphilis, for the reasons that it was shortly followed by an outbreak of well-marked specific efflorescences on various parts of the body, and, moreover, there was a transformation of the eruption upon the head, into infiltrated lesions presenting a distinct syphilitic character. The eruption first appeared on the face in the form of an erythema which was covered with vesiculo-papular efflorescences. Later a similar outbreak occurred on the nape of the neck. The vesiculo-papules broke, leaving excoriated surfaces of a diphtheroid character, from which there exuded an exceedingly abundant, foul-smelling discharge. Soon after, vegetating growths made their appearance, which upon the bearded parts of the face were quite exuberant and resembled condylomata acuminata. Those upon the neck, formed more discrete, tuberous prominences and had the appearance of condylomata lata; while upon the upper parts of the face, the elevations were nummular and had comparatively smooth, though somewhat lobulated surfaces. After a week or two, the erythematous areas, which formed the bases of the vegetating lesions, became the seats of a gradually increasing, copper-colored infiltration. The palms and corresponding surfaces of the fingers, were covered with a deep red, sharply circumscribed erythema, which was followed by lamellar desquamation. A similar eruption occurred in patches upon the soles. The finger-nails were all more or less affected with onychia sicca. Upon the body and limbs several crops of well-marked syphilitic papules succeeded each other, and finally all the manifestations yielded rapidly to mercurial treatment. The preliminary eruption in this case was characterized as an erythanthema dependent in some way upon the specific disease. Other instances of erythematoid eruptions occurring incidentally to syphilis, were referred to as being more or less analogous to the above cited case.

Allusion was made to syphilitic roseola as a possible case in point; then to the preliminary erythematous eruptions observed in hereditary syphilis, *érythème précurseur* of the French, and also to certain forms of coincident or preliminary erythema as described by Hebra, Neumann, Danielssen, Lipp, and Finger. Attention was next called to that class of symptoms which have been characterized as syphilitic erythema nodosum, and three cases of this affection were reported, in one of which the erythematous eruption was apparently succeeded by a syphilitic infiltration which pursued a course similar to that of a breaking-down gumma of the skin.

Finally it was attempted to define more precisely the etiological relations of these various erythematoid eruptions occurring in connection with, and probably as a consequence of, syphilis. It was maintained that probably they were not equivalent in their mode of origin to the syphilodermata, but rather to certain angioneurotic affections, which they closely resembled. The true syphilodermata are always characterized by a specific infiltration and are probably the result of a determination of the materies morbi to the surface. They are, therefore, pathognomonic of syphilis. The erythanthema syphiliticum, on the other hand, is only an indirect effect of the syphilis, the result of reflex irritation of the skin from the action of the disease upon nervous centres, and therefore not pathognomonic of syphilis. The fact that this might be followed by a true syphilitic infiltration *in situ*, was regarded as analogous to the effect sometimes observed of traumatic irritation in syphilitic subjects, where local injuries become the seat of specific infiltrations.

DR. I. E. ATKINSON, of Baltimore, said that as regards pathognomic syphilitic eruptions, a great deal of caution must be exercised. Lesions similar to those described by Dr. Bronson are not of excessive rarity in cachectic subjects and in cases of malignant syphilis, but in his experience, they have always been manifestations of late or tertiary syphilis.

DR. J. C. WHITE, of Boston, remarked that the occurrence of the forms of disease which have been described are so rare in syphilis, we know so little of the nature of erythema nodosum and its causes, and so little of the nature and causes of so-called erythema herpetiformis, which he thinks should be called erythema multiformis, that it seems to him that we must have some more exact data before we can regard these affections as a necessary sequel of syphilis and as anything more than accidental occurrences. A causal relation existing between these conditions and syphilis has not been proven. The early roseolous exanthematous condition of the skin in syphilis is of sufficiently frequent occurrence to be looked upon as a distinct feature of syphilis. This is wholly unlike the rare forms of dermatitis which have just been described.

DR. F. B. GREENOUGH, of Boston, stated that syphilitic roseola seemed to him to be decidedly distinct from other forms of congestion of the skin, especially in one particular, that is during the subsidence of the congestion little points of distinct congestion continue for a long time. These appear to represent the follicles. The points of pigmentation are also an almost constant occurrence. This he had not seen in other forms of affection of the skin.

DR. G. H. TILDEN, of Boston, held, in the present state of our knowledge, that it would be more philosophical to consider the appearance described as accidental than as dependent upon the specific disease.

DR. I. E. ATKINSON, of Baltimore, then read a paper on

RÖTHELN,

which was based upon a review of the literature of the subject, and a study of the reported cases. The disease was regarded as distinct from measles and scarlet fever. The period of incubation varies between two and three weeks. In many cases there is no prodromal stage. There may, however, be prodromata for twelve or twenty-four hours. Catarrhal symptoms are generally absent, but they may be present. Sometimes there is congestion of the throat. Swelling of the lymphatic glands is a peculiar and marked symptom. This swelling is painful, but does not pass on to suppuration. In many cases fever is absent. The eruption first appears on the forehead and face, and in the course of a few hours spreads to other parts of the body. The eruption is more or less irregular, being more intense in some

situations than in others. From the beginning to the disappearance of the eruption is usually three or four days. In the greater number of cases, desquamation fails to occur. Complications and sequela are not unknown, the most common being bronchitis, pneumonia, and gastro-intestinal disorders. Renal affections may follow this disease. Relapses occasionally occur, but not later than the end of the second week. The prognosis is almost always favorable.

The only difficulty in diagnosis is in connection with measles; and in isolated cases a thorough consideration of all the points is essential to a correct conclusion. Very little treatment is required, except in the presence of complications.

On account of the confusion existing as to the nomenclature of this disease, he suggested that rubeola be accepted as its proper title, and that it might be known in popular language as epidemic roseola.

THE PRESIDENT stated that several years ago he suggested that measles be called morbilli, and rubeola or rötheln be used to signify what is termed German measles, and roseola be reserved as the title for the rose-colored spots seen in syphilis and other conditions. There did not seem to be any necessity for the introduction of a new term.

DR. G. H. FOX, of New York, then presented a

REPORT OF A CASE OF LYMPHADENOMA (MYCOSIS FUNGOIDE), AND AUTOPSY.

Mrs. G., aged thirty-three years, the mother of six children. During pregnancy, in the summer of 1881, she suffered with general pruritus, which passed away after confinement in October. A year later, small, flattened, circular tumors appeared in the axillæ and on the breasts. These became moist, and were accompanied with a burning sensation. The eruption disappeared from these situations, and reappeared upon the back and other portions of the body. After the birth of her last child, in February, 1885, a tumor developed at the inferior angle of the left scapula. The lesions on the other parts of the body disappeared, with the exception of two spots on the finger and one on the left cheek. The tumor on the left scapula gradually softened and disappeared.

The patient was admitted to the hospital in October, 1885, and was fairly well nourished. There were at this time numerous tumors over the body, some of which were superficially ulcerated. The worst tumors were on the breast. Hypodermatic injections of Fowler's solution were used without benefit. Chaulmoogra oil was given in increasing doses until forty drops, four times daily, were taken without causing any improvement. The patient died in April, 1886. The microscopical examination gave the usual appearances of these growths. The internal organs were found to be normal.

DR. G. H. TILDEN, of Boston, remarked that, one year ago, he reported a case of this disease. He then said that it was not sarcomatous. Rindfleisch states that he has found a distinct micrococcus inside of the bloodvessels in this connection, and recently this has been confirmed by another observer. It looks as though what we ordinarily know as malignant lymphoma, affecting the lymphatic glands, with deposits in other parts of the body (Hodgkin's disease), is one of the infectious diseases. He should not be surprised to find that this mycosis fungoide is a variety of the same disease, and that it is nothing but an acute infectious disease.

A NOTE RELATIVE TO THE BULLOUS ERUPTION OCCURRING AFTER INGESTION OF IODINE COMPOUNDS

was, in the absence of the author, DR. J. N. HYDE, of Chicago, then read by the Secretary.

Case I.—An infant, seven months of age. Six weeks before coming under observation the child had suffered from a febrile attack, the exact nature of which was not known. Three weeks later the eruption made its appearance. The lesions at first presented the appearance of chicken-pox. The child's face, the dorsal aspect of the hands, forearms, and the scalp, were covered with isolated whitish, split-pea, to marble-sized, flattened, slightly umbilicated lesions, resembling molluscous tumors. The contents of the lesions were inspissated, thick, and grumous, and of such consistency that they did not escape on rupture of the sac. It was learned that iodide of potassium in one grain doses had been administered for the febrile attack. On the discontinuance of the iodide and the use of antiseptic powder, the lesions rapidly disappeared.

Case II.—A lad, fifteen years of age, who had recently undergone an operation for necrosis of the right femur, developed an eruption involving the entire body. There were two distinct sets of lesions. That which predominated was composed of annular circinate plaques, varying in diameter from several centimetres to half a metre. There were also here and there, particularly about the finger-ends, distinct blebs. The patient had been taking iodide of potassium in fifteen grain doses. This was discontinued, and the eruption speedily disappeared.

There are two distinct types, the bullous and the quasi-bullous eruption, produced by the ingestion of iodide of potassium. In the first form the patients are often well advanced in years, often cachectic, and frequently affected with syphilis or other grave disease. In what may be regarded as a second sub-form of this exanthem, there are dimorphic or polymorphic symptoms. Here bullæ are commingled with papules, tubercles, and other patches of disease. The speaker then described other cases of similar eruptions described by various writers, and, in conclusion, presented the following interrogative propositions:

1. Are there not three sub-forms of the bullous exanthema developed in certain individuals after the ingestion of iodide of potassium?

2. Is not the first and most common of these to be generally recognized in persons of advanced age and cachectic condition, the rash being then present in the form of typical bullæ?

3. Is there a second and still rarer sub-form, in which the eruption is displayed in dimorphic or polymorphic manifestations; typical, perfect bullæ being then mingled with papules, tuberoles, scarlatiniform maculations, or with other and different lesions?

5. Is there not a third and rarer sub-form, the quasi-bullous rash, to be most frequently recognized on the face and dorsal aspect of the hands and forearms of infants and children, in which the lesions are semi-solid, slightly umbilicated, and filled with inspissated, yellow-

ish matter, and which may shrivel and desiccate on the suspension of the drug inducing the condition?

5. Is this last described lesion one to be recognized solely as the result of the ingestion of iodide of potassium, never under other circumstances, and one as peculiar to the special condition it represents, as is the gumma to syphilis?

Dr. R. W. Taylor, of New York, said that while the most general eruption produced by iodide of potassium is an acneform exanthem, yet it may cause dermatitis with multiform lesions with bullæ, which may contain serum, pus, or even blood. He thought that some of the cases of extreme dermatitis multiformis which have been described have been due to this cause.

He described a peculiar form of iodine intoxication in a case of gummatous infiltration of the pharynx, in which iodoform had been resorted to as a local application. In the course of two hours it produced a diffuse eruption of the face, neck, and hands; on the hands it assumed an eczematous character.

Dr. J. E. Graham, of Toronto, related the history of a case similar to that described by Dr. Hyde. A man, twenty-two years of age, had contracted syphilis two years previously. Noticing some pimples on his face he secured a preparation of iodide of potassium containing five grains to the dose. The speaker saw him two days after he had begun to use this preparation. He then had a bullous eruption, principally upon the face and neck. At that time it was thought that it was a tertiary manifestation, and he increased the dose of iodide to fifteen grains. Two days later, the eruption on the face was much increased and recognizing the cause of the condition, the remedy was stopped and the eruption rapidly disappeared.

Dr. I. E. Atkinson, of Baltimore, said that he saw a case, one year ago, of what was supposed to be malignant syphilis. The patient had had syphilis, and had been put on the use of iodide of potassium. The lesions continued to increase and after the iodide had been taken for six months he saw the case. There was an enormous formation of scar-tissue over the face and neck. In addition there were bullæ and elevated infiltrated plaques. The appearances presented were unlike those produced by syphilis, and he thought that they were due to the iodide of potassium. The drug was stopped, and in six weeks the ulcerations had healed; the cicatricial tissue, of course, remained, Too much stress cannot be laid upon the dangerous conditions which may follow the administration of the iodides.

Evening Session.

R. W. Taylor, M.D., of New York, read a paper on

PRECOCIOUS GUMMATA.

The following conclusions were presented:

1. Like the osseous affections, the affections of the nervous system and malignant syphilides in general, the gummata syphilæ may be precocious in appearance, occurring as early even as the second month of infection.

2. Of the precocious gummatous syphilide or gummata, there are three quite clearly marked forms, first, the early, general, and copious form; second, the more localized form, which may invade several regions, is usually symmetrically distributed and sometimes even is confined to one region, particularly one side of the face or scalp and the roof of the mouth; and thirdly, a form in which more or less severe neuralgias precede and accompany the eruption, which in many particulars resemble simple erythema nodosum, but which in its etiology is not in any way related to this simple form of eruption, but is a direct outcome of the syphilitic diathesis.

3. That these precocious gummata partake in general of the features of those of later forms, but that they differ in the more acute invasion, in a much more rapid course, and are usually not as profound and destructive in their action as the classical eruption.

4. That of these precocious forms of gummata, there are found to be two varieties, one a non-ulcerative or resolutive, the other ulcerative.

5. That in the treatment of these precocious syphilides, a combination of mercury and iodide of potassium is much more efficacious than is mercury alone.

Dr. F. B. Greenough, of Boston, presented some

CLINICAL NOTES ON SCABIES.

For thirteen years he had had the opportunity of studying a large number of cases of scabies, and had been much interested by the rapid increase in the number of cases seen during the past few years. They had rapidly increased from 3 in 1879, to 160 during the last year. He had during the past year also made inquiries as to the number of members of the same family of whom the patients could give an account as being similarly affected, and had records of 110 such cases, which, with 6 cases seen in private practice, made a total of 276 cases that had come under his cognizance during the past year. The percentage of cases of scabies had increased from 3 per cent. in 1876 to over 13 per cent. during the past year. During the war, the disease naturally increased and the medical officers got a knowledge of it, which they carried with them into private practice after the war was over. The disease being properly treated became so much less frequent that the new generation of physicians saw little of it, and each case not recognized proved a focus of contagion for a large circle. Four-fifths of the cases seen were between five and thirty years of age, and only four cases were over sixty years of age.

The facts which were especially noticed were the few cases in which typical burrows could be found; the great constancy of the manifestations on the penis in male subjects; and the success of treatment. He had used almost entirely an ointment consisting of two parts of carbonate of sulphur, one of carbonate of potash, and three of petroleum ointment, simply cautioning the patients against applying it to inflamed and pustular localities. He referred to the distribution of the eruption as of importance in the diagnosis of difficult cases.

Dr. A. R. Robinson, of New York, said that in some cases in which there was difficulty in the diagnosis, he had reached a positive conclusion by opening a vesicle and examining its contents under the microscope, and finding the young acari or the feces.

Dr. L. N. Denslow, of St. Paul, had seen a number of cases in which no burrows could be found, but under treatment suitable for scabies, they had recovered. He employs thorough scrubbing from head to feet, followed by the application of sulphur ointment. He considered

the complaint known as prairie itch nothing more than scabies.

Dr. E. B. Bronson, of New York, remarked that in many cases he had depended largely upon the elongated character of the efflorescence in making the diagnosis. For three months he had treated all cases of scabies with naphthol, using a fifty per cent. preparation and making one thorough application. This has produced a satisfactory result.

Dr. S. Sherwell, of Brooklyn, had also noted an increased number of cases of scabies, and a large proportion of the cases had been among Scandinavians, leading him to think the increase might be due to want of thoroughness in the cleaning of the ships in which emigrants are brought to this country. As a prophylactic, he directs the patient to sprinkle on the sheet of the bed a teaspoonful of dry sulphur. This acts as a disinfectant and is unpleasant to the acaris.

Dr. H. W. Stelwagon, of Philadelphia, presented some

CLINICAL OBSERVATIONS REGARDING THE VALUE OF RESORCIN, ICHTHYOL, AND LANOLIN IN CUTANEOUS DISEASES.

Resorcin, in eczema, is rarely of benefit, but possesses some power over the itching. For this purpose a five per cent. ointment is useful. In greater strength it is irritating. In tinea sycosis it has proven of some value in ten to twenty per cent. strength. In tinea tonsurans it is inferior to the remedies usually employed. In one case of leg ulcer, healing took place under its use. In a second case, no effect was produced. In seborrhœa and alopecia dependent upon this disease, a lotion consisting of a drachm of resorcin, one or two drachms of castor-oil, five minims of Peruvian balsam, and four ounces of alcohol, was of value. In tinea versicolor, it was found less useful than a solution of hypophosphite of sodium. In psoriasis and in one case of lupus erythematosus the result was negative. In one case of superficial epithelioma, a fifty per cent. ointment produced a good result, in a second case a fair result, and in a third the result was negative. In a case of favus, a twenty-five per cent. ointment, used for two months, produced no decided effect.

Ichthyol. In a small proportion of cases of rosacea and acne vulgaris, a ten to twenty per cent. preparation usually was found beneficial. In eczema it was valueless and irritating. In furunculus it acted with good results in three cases, when applied as a twenty per cent. plaster. In the fourth case it had no effect. It was of service in psoriasis and also in a case of lupus erythematosus. In favus it was used without effect.

Lanolin. In some cases, as an ointment base, this is superior to the ordinary fats in use. Where a simple protective action is desired, it is inferior to vaseline, cold cream, or lard. In chronic cases, where there is infiltration and a degree of penetration is desired, lanolin is especially valuable. The writer stated that, according to Liebreich, a lanolinum purissimum is now manufactured in which the cholesterin ethers are absent. The main disadvantage of lanolin, as now manufactured from sheep's wool, is the strong sheepy odor. In a few acute and subacute cases of eczema, lanolin, for some reason, proved irritating. As a rule, however, it is bland and unirritating.

(*To be concluded.*)

THE AMERICAN SOCIETY OF MICROSCOPISTS.

Annual Meeting, held at Chautauqua, New York, August 10, 1886.

(Specially reported for The Medical News.)

A very successful meeting of this Society was held this year at Chautauqua, and we present abstracts of the papers read which were of medical interest.

Dr. George W. Lewis, Jr., of Buffalo, presented

A REPLY TO SOME OF THE ARGUMENTS THAT HAVE BEEN ADVANCED TO OVERTHROW THE COMMA-BACILLUS OF ASIATIC CHOLERA.

On the 25th of July, 1884, Dr. Koch addressed the Imperial German Board of Health at Berlin on the subject of cholera and its bacillus. He then expressed the belief that the comma-bacillus bears a causal relation to the cholera process: that it gains entrance by the mouth, and depends for a safe passage through the stomach upon some disordered condition of that organ or its function; that the real seat of the disease is the lower part of the ileum, including Peyer's glands; and that up to that time inoculation experiments had given only negative results. He pointed out, moreover, a striking relationship between the course of the disease and the life history of the organism both as regards the remarkably short time required for it to reach a full development, and the equally rapid decline which immediately sets in. His statements were the more valuable because they were based upon some three hundred autopsies performed in the height of cholera epidemics in France, Egypt, and India, and because, not satisfied with even this, he had visited the long stretch of country known as the Delta of the Ganges, where the disease prevails to a greater or less extent throughout the entire year.

From the date of that memorable meeting to the present time, the comma-bacillus has been a favored target at the hands of the skilled and unskilled in this branch of medical research. To attempt an answer to some of the so-called arguments that have been advanced to overthrow the comma-bacillus and its relation to the cholera process would be a mere waste of time, for the promulgators of these theories show by their methods of reasoning their utter ignorance of even the principles upon which the science of bacteriology is based. Such, for example, are those who claim a spontaneous origin for this disease, and likewise those who assert, apparently without any foundation, that the comma-bacillus is only a transition stage in the development of the organism which really causes the pathogenic changes. This idea, he believed, grew out of the fact that inoculation experiments are not altogether positive in their results, although it is generally conceded that the comma-bacillus is in some way inseparably associated with the disease. Those who dissent from the idea of its being the *causa causans* prefer to class the comma-bacillus itself as the harmless stage in the life history of the organism which at an earlier or later stage constitutes the materies morbi. So far as he knew, there is no instance on record of the transformation of one kind of bacteria into another, and in so brief an existence as that of the comma-bacillus, where the stages in its life history must necessarily follow each other in rapid succession, there could not be one pathogenic stage

while all the rest are harmless. It is true that some bacteria—for example, anthrax bacilli—lose their pathogenic properties when subjected to the influence of certain reagents, but a change of form has never been noticed.

The above, however, is an illustration diametrically opposed in character to the one of which we are speaking. Here we would have a harmless intestinal bacterium take on instead of throw off its pathogenic characteristics. Another point not to be overlooked in this connection is that the proportion of comma-bacilli to other intestinal bacteria has been rated as high as ten to one, which would imply that during its brief stage of harmlessness its power to multiply is increased tenfold. This, of course, is contrary to every known law.

Another theory is that the comma-bacillus is the scavenger rather than the cause of the disease—that is, conditions are created by the disease through which, among the many bacteria to be found in the intestine, one kind or another is changed and assumes the qualities observed in the comma-bacillus. The explanation given in the above case is equally applicable here. Our knowledge of bacteria shows us that, so far as form is concerned, they are all remarkably constant. If they were not, successive cultivations outside of the body would cause them sooner or later to revert to their original form. The comma-bacillus has been carried as high as the twentieth cultivation in various nutrient media, and yet no alteration either in form or manner of growth has been observed. If it were only a transitional stage of some bacterium, that fact would certainly be revealed during successive cultivations. Likewise, if it is the scavenger of the cholera process, then as soon as it is separated from the cholera process the germs would cease to flourish. But it is constant throughout.

Klein expresses the view that the cholera process favors the growth of comma-bacilli by preparing a nutritive soil for them, and on this hypothesis he endeavors to explain the striking increase of this particular kind of bacteria. If this is so, then we must start with the understanding that the comma-bacillus exists in the perfectly healthy body; but the most searching investigations have failed to reveal the slightest trace of an organism that in any way resembles it either in form or manner of growth. Moreover, in cases which eventually terminated in recovery, there was manifestly a decrease in the number of comma-bacilli corresponding to the stage of convalescence.

Of course, if it were possible to induce the choleraic condition in animals by the inoculation of comma-bacilli, there would be no room for controversy as to the causative power of this organism. Even if by feeding appreciable quantities of this form of bacteria any derangement of the digestive process were brought about, it would at least give encouragement as to its causative properties. So far from having either of these effects, its action is not perceptible. This seems a strong barrier, and were it possible to bring to account the case of a single animal fallen ill with the disease during any of the epidemics, it would certainly be an insurmountable obstacle to the consideration of the causative relation of the comma-bacillus. But from all the quarters that have been visited by epidemics come unanimous reports as to the exemption of animals from a condition in any way resembling cholera. This carries with it a good deal of weight, which alleviates in a degree the disappointment resulting from the failure of inoculation experiments. It was evident, from careful examination of the intestines, that the comma-bacilli had been killed during their passage through the stomach; in fact, few were found in the intestinal canal, being confined, for the most part, to the walls of the stomach. It is probably true, too, that if the digestive tract of man is free from derangement, he will likewise be able to resist the disease.

While under Koch's tuition at Berlin in the winter of 1884, Dr. Lewis busied himself particularly in the line of inoculation experiments, being quite as sceptical as any one could be in regard to the claims made for the comma-bacillus. The animals used for this purpose were white mice, guinea-pigs, and rabbits. No effect whatever was produced by feeding a pure culture, but when the bacilli were introduced directly into the duodenum, the guinea-pigs and rabbits, some six hours later, manifested most of the symptoms of cholera infection. The mice, however, exhibited no trustworthy symptoms, dying apparently from indisposition. Upon examination of the intestines after death, large numbers of cholera bacilli were found in the region of Peyer's glands, the glands themselves being enlarged and inflamed. These appearances were very distinct in the guinea-pigs and rabbits, but scarcely perceptible in the mice. From a physiological standpoint, there is no apparent reason why the mice should be affected differently from the guinea-pigs and rabbits, and yet throughout Germany experiments upon mice have been unsatisfactory. The small size of the animal, and the consequent care that must be taken in reaching a desirable point of inoculation, will explain in part the failure in a large number of cases. This is evident from the fact that a great many of the mice die from peritonitis rather than from any pathological effect produced by the bacteria.

If we assume that a disease is caused by a specific germ, we cannot think of an autochthonous origin, emanating from any particular locality. Such a specific organism must follow the laws of vegetation, just as the most highly developed plant. It must always propagate itself from something of the same nature, and cannot spring up at haphazard from other things or from nothing. In the case of the comma-bacillus, the home of which has been quite clearly defined, we are forced to trace back the disease that depends upon it to special localities from which this specific microörganism is brought to us.

Mr. Eugene Rau read

AN ACCOUNT OF MICROSCOPICAL EXAMINATION MADE IN TWO FATAL CASES OF TRICHINOSIS IN BETHLEHEM, PA.

On February 8, 1886, samples of pork were submitted to him for examination, the use of which, it was supposed, caused the illness of a family consisting of man and wife and two daughters, five and thirteen years of age. The pork was found to contain trichinæ varying in numbers from two to six, and occasionally as many as eight in a field view. The meat had been freely used for a week from January 6th. An $\frac{8}{10}$ objective with an A eye-piece was used on the microscope for all the examinations made; the field view being about $\frac{1}{12}$ of an inch in diameter.

The daughter, aged thirteen, died after an illness of

five weeks, and an examination of a small portion of the deltoid muscle revealed trichinæ to the number of twelve to eighteen, and in one instance as many as forty-two were counted in the field view. The results of these examinations conclusively show the cause of the disease; no other portions were examined.

In the mother, aged thirty-seven, who died after an illness of nearly eight weeks, the deltoid muscle was found to contain three to nine, the rectus femoris two to six, and the diaphragm one to three trichinæ to a field view. The lungs, heart, liver, spleen, and kidneys were not found to be infected.

The pork used was home-raised, and, according to the owner, the animal did not at any time show signs of being unwell. An examination of two other hogs raised on the premises was made, but no trichinæ were found. For several days, while in water, the human trichinæ showed signs of life, coiling and partly uncoiling when freed from the muscle fibre. Those in the pork being in the encysted condition, showed no activity when separated and placed in the same conditions as the former.

The trichinæ in the deltoid of the daughter were found free in the muscular fibres, while those in the muscles of the mother were encysted. Eight photographs were submitted; all with the exception of one were made with a $\frac{2}{3}$ objective without an eye-piece. Four are from the human subject and four from the pork. The length of the trichina uncoiled was $\frac{1}{30}$th and diameter $\frac{1}{700}$th of an inch.

THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

Annual Meeting, held at Buffalo, August, 1886.

(Specially reported for THE MEDICAL NEWS.)

THE Annual Meeting of the American Association was held at Buffalo this year, and we present abstracts of the papers of medical interest which were read.

DR. BURT G. WILDER, of Ithaca, read a paper on

HUMAN CEREBRAL FISSURES; THEIR RELATIONS AND NAMES, AND THE METHODS OF STUDYING THEM.

It embodied the results of a study of the subject which has been wholly interrupted since 1873, when a paper on the fissures of the carnivora was read before the Association. He believed that, for the present, the attempt to refer the human fissures to a series of arches like those of some carnivora, has not been of use to students, and that the beginner must learn their relative positions and names as a task for the memory alone.

It is easier, however, to treat the cerebral surfaces as regions of an unexplored country, to determine directions and landmarks, and to learn certain fissures before others. The landmarks are the callosum, the Sylvian fissure, and the margin of the hemicerebrum. The first fissures to be learned are the interlobar, then the constant, intergyral, with ental correlatives, then those with no such correlatives; finally, the inconstant, intragyral fissures. He enumerated forty-six fissures, more than have been designated by any previous writer.

His views as to the relations of the fissures were mostly indicated by diagrams with the names thereon. The latter are mostly mononyms, selected or formed from names in common use. The following fissures were discussed in detail: presylvian; exoccipital; lambdoidal; paracentral; paroccipital; meditemporal; precentral; post-central; adoccipital; intermedia; subsylvian. The gyral names were discussed briefly.

In conclusion, he urged that, in contravention of the view and practice of Gratiolet, Meynert, and some others, the brains of monkeys be disregarded as preliminary to the human, and that fœtal brains be preserved and carefully studied.

DR. C. S. MINOT, of Boston, then read a paper on

HOMOLOGUES OF SEGMENTATION OF THE OVUM IN VERTEBRATES.

The ovum divides first into two sets of cells, the small ectoderm and the large entoderm cells. The line of junction between the two is the ectoental line, part of which forms by concrescence the primitive streak, and its homologues. The ectoderm is primitively many layered, and becomes one layered later. The inner cell mass of the mammalian ovum is the true ectoderm, while the supposed ectoderm of the mammalian blastodermic vesicle is really the entoderm. The mesoderm grows out from the ectoental line. The entodermic cavity is always distinct from the segmentation cavity, but the view hitherto prevalent in regard to the homologies of the mammalian blastodermic vesicle, make the two cavities identical. All the variations can be correlated with the greater or less development of the yolk.

PROF. J. H. PILLSBURY, of Smith College, Northampton, Mass., read a paper on

AREAS OF FORM AND COLOR PERCEPTION IN THE HUMAN RETINA.

After describing the methods of observation and apparatus used, the paper discusses the following points.

1. Relation between myopia of the eye and the extent of the area of form vision.

2. Relative extent of areas of form and color perception.

3. Relative extent of areas of color perception for different colors.

4. Some curious irregularities of areas of color perception.

DR. C. S. MINOT, of Boston, offered some remarks

ON THE DEVELOPMENT OF THE HUMAN CHORION.

The human chorion comprises at the third week of gestation two layers: 1, a mesodermic layer consisting of rounded cells embedded in a glistening matrix; 2, an ectodermal pseudoepithelium. The first changes, during the second month, into spindle-celled connective tissue with large, round, granular cells of unknown origin scattered through it. The second undergoes a complicated metamorphosis. The cells proliferate in numerous patches forming several layers; the patches enlarge and fuse to a greater or less extent. The basal layers of the thickened portions give rise to Langhan's cellular layer, and the outer parts undergo a remarkable hyaline degeneration to produce Langhan's fibrin layer. The chorionic epithelium is, therefore, not lost, but only metamorphosed.

DR. H. P. BOWDITCH of Boston, made some remarks on the

VASOMOTOR NERVES OF THE LIMBS.

In most of the recent experiments on the vasomotor nerves of the limbs, the temperature of the skin has

been taken as the index of vasomotor activity. It is evident, however, that by this method transitory changes cannot be recorded and quantitative results cannot be obtained. In experiments made with the plethysmographic method, to which these objections do not apply, it was found that either a constriction, or a constriction followed by a dilatation, or a dilatation of the vessels of the leg may be produced by an electric stimulation of the sciatic nerve. The character of the result depends largely upon the strength and rapidity of the induction shocks used as a stimulus. In the following table are given the results of 909 observations of the effect of stimulations of the sciatic nerve, with induction shocks of varying intensity and rate. The figures in the columns headed —, — +, and + show in what per cent. of the total number of observations the effect of the stimulation of each rate and strength was respectively a constriction, a constriction followed by a dilatation, and a dilatation.

	Weak.				Medium.				Strong			
Rate of Stimulation.	No. of observations	Per cent.			No. of observations	Per cent.			No. of observations	Per cent.		
		—	— +	+		—	— +	+		—	— +	+
0 – 4 in 1″	108	9.3	57.4	33.3	218	7.8	69.7	22.5	142	6.3	69.7	23.9
5 – 16 in 1″	69	31 9	60.9	7.2	153	28.8	58.8	12.4	109	5.5	89.9	4 6
30 – 64 in 1″	62	48.4	50.0	1.6	40	50.0	50.0	0.0	8	37.5	62.5	0.0

It will be observed that with each rate and intensity of stimulation, the result, in at least one-half of the observations, is a constriction, followed by a dilatation; (2) that with an increasing rate of stimulation, the proportion of cases giving a simple dilatation diminishes, while (except with strong stimulations) that of cases giving a simple constriction increases.

With slow irritations it was found that dilatations are more readily produced with feeble than with strong irritations. Experiments with animals whose nerves had been cut several days previously showed that degeneration of the nerve caused the loss of its constricting earlier than that of its dilating power.

It thus appears that the sciatic nerve contains fibres which both constrict and dilate the vessels, but the former effect being more prompt than the latter, both in its appearance and disappearance, the two effects never neutralize each other.

A fresh nerve with a strong and rapid stimulation, offers the best conditions for producing constriction. A degenerate nerve, with a feeble and slow stimulation, offers the best conditions for producing dilatation.

(*To be continued.*)

CORRESPONDENCE.

THE OBSTETRICAL SECTION OF THE BRITISH MEDICAL ASSOCIATION.

The meetings of the British Medical Association, at Brighton, have just terminated with the Mayor's ball on Friday evening, and a temperance breakfast early Saturday morning, at which at least one hundred and fifty members were present. Throughout the week the city was crowded with medical men from all over the English-speaking world.

The addresses, made in the mornings before the whole Association, by Withers Moore, M.D., F.R.C.P., Major J. S. Billings, M.D., F. A. Humphrey, F.R.C.S., and E. D. Mapother, M.D., were equal to any the Association has listened to in former years, while that of Dr. Billings in particular was both instructive in the highest degree, and full of the happiest hits, never allowing the interest of the audience to flag for a moment. The afternoons were devoted to the meetings of the Sections.

Your correspondent's attention was confined almost exclusively to the work of the Obstetrical Branch, with the exception of the addresses made upon the subject of the "Surgery of the Liver," before the Surgical Section, on Thursday afternoon, by George Harley, M.D., F.R.S., J. K. Thornton, Esq., A. Willett, Esq., and Lawson Tait, Esq. These latter communications took the form of distinct papers, detailing the original work of the authors, and they touched upon many widely diverse points. Dr. Harley related cases of acute hepatitis in which he had, with perfect results, punctured the liver with a large trocar about six inches in length, and, as in one instance, drawn off twenty ounces of blood. He also recommended multiple punctures of the capsule in hypertrophic cirrhosis, which he had also found a valuable remedial expedient. Mr. Thornton brought before the Society all the cases in which he had found it necessary to interfere with the liver structure in his abdominal sections. His conclusion was that the liver was far more tolerant of injury than is generally believed by surgeons.

Mr. Willett related a case of cholecystotomy. Mr. Tait followed with a brief address, the text for which was furnished by three tables including the fifty cases in which he had operated upon the liver. The tables were in the hands of the members in the form of proof-sheets. Seven of these cases are set down as "exploratory incision," two of which revealed "cancer," one of the liver, and one of the gall-bladder; three are labelled "tumor," one "hepatic colic," and one "miliary abscess." One "tumor" died of colloid cancer. Following these are "thirteen cases of hepatotomy," all recovered; nine of them were performed for "hydatids of liver," two for "cyst of liver," one for "tumor of liver," and one for "gall-stones." The youngest patient on the list, age seven years, is found here, for "hydatids of liver." The table concludes with "thirty cases of cholecystotomy," twenty-six of which were "gall-stones," with one death. One was a case of "cholœmia," and two of "distended gall-bladder," and one of "suppurating gall-bladder."

The whole table is suggestive, and capable of some

interesting analyses. More than half the operations were undertaken for gall-stones. The average age of those operated upon was nearly forty-five years (44.8), and more than forty per cent. (40.7) were in the forties, while nearly sixty-three per cent. (62.9) were between thirty-five and fifty-five years of age.

The ages of the cases operated upon for hydatids differ more widely than those of any other class, but the average is only thirty-one years, the extremes being seven and sixty-three.

Dr. Alfred Meadows, President of the Obstetrical Section, delivered the opening address on Wednesday afternoon at two o'clock. He first spoke of the tendency in England, Germany, and America to divorce obstetrics and gynecology, and then eulogized the present status of our science, referring more in detail to some of the most recent achievements. The reaction against craniotomy in Great Britain seems to be of the strongest nature. Dr. Meadows spoke of it as an operation "barbarous and repulsive to every religious sentiment," while the Porro method is a distinct advance in the direction of saving life. He quoted Tait's dogma, that in the latter operation there was at least a chance of saving the life of the child, while the dangers of craniotomy were as great to the mother as in Porro's operation. To this frightful operation —craniotomy—nearly two thousand lives and some hundreds of mothers are sacrificed in England yearly.

Dr. Meadows proceeded to dwell most ably upon the moral and scientific bearings of the case, and urged the fact upon the members that here, in this particular field, must we look for some of the greatest advances in the future.

Removal of the *uterine appendages* is an erroneous term, as the *uterus* is the appendage to the organs in question. The startling statistics of this most recent innovation in gynecological surgery call for comment. The subject has important moral bearings, and like all else encroaching upon the moral world, is apt to provoke angry discussion. It clearly has its legitimate field in certain cases of, by other means incurable, nervous disease, in cases of rapidly growing fibroids, and, without question, in distinctly developed ovarian and tubal disease. The operation ought also, in cases where birth *per vias naturales* cannot be accomplished, to take the place of the Porro operation and craniotomy and the many disgusting methods recommended to prevent conception. We must in all these cases aim at greater diagnostic precision, and not be too lavish in our selection of those deemed fit for operative interference.

Dr. Robert Barnes read the first paper on the subject "Alternatives to Craniotomy." This operation was so frequent in Tyler Smith's time, that it numbered one in every three hundred and forty labors, and at one time the perforator was more frequently used than the forceps. The deformities which call for craniotomy arise for the most part in childhood, and, as has been shown in one English town, are to be prevented by hygienic measures, and anti-syphilitic precautions.

Next, after hygiene, comes the induction of labor, either before the viability of the child, or during the last three months; and from the thirty-sixth to the fortieth weeks we have often the alternative of turning. When the patient has arrived at full term with a living child which cannot be brought alive through the pelvis, the alternatives are two, craniotomy or Cæsarean section. In extreme cases of pelvic deformity the latter, or some kindred method, becomes a necessity, but in pelvic contraction of about three inches embryotomy ought not to give a greater mortality than ordinary labor, and, until the chances from the Cæsarean section equal those of embryotomy, the question cannot be considered as solved in favor of the former, which abandons the old moral law that the mother's life is more important than that of the unborn infant. Will the Cæsarean section be improved up to this point? In from three to three and a quarter inch deformed pelves perform craniotomy, and in future induce premature labor. This measure will only be abolished with the triumph of hygiene.

Dr. Kinkead, of the Royal Infirmary of Dublin, ably considered the question, "Can the maternal mortality of the Cæsarean section be reduced to that of craniotomy?" The difficulties in the way of an accurate comparison are great. Consistently with the showing of Parry that in cases of great deformity (two and a half inches) the maternal mortality of the two operations are equal, we should choose the sectional method. The mortality of the Cæsarean section is great, but it is due to the delays, and the blame for this must fall on those teachers who ever assert that it is an operation of almost necessary fatality. In those cases in which no other attempts to deliver have been made, and the operation has been undertaken within the first twenty-four hours, Dr. R. P. Harris has shown that the maternal mortality of the Cæsarean method is but twenty-five per cent., while all tables of craniotomy in two and a half inch pelves show a mortality of from thirty-seven and a half per cent. (Parry) to seventy-five per cent. in carcinoma of the uterus. Shock, hemorrhage, peritonitis, and incarceration of the intestine are the prime factors in causing death after the Cæsarean method. The first is relieved by early operation, the second by elastic ligature, and the second and third and fourth by close approximation of the wounded surfaces.

In the course of the discussion which followed these two papers, Dr. Lusk, of New York, made a very clear statement of the present status of the subject. Deformities below three inches are rare in New York. That method is a welcome one which will relieve us of the horrible operation—craniotomy—which he has often had occasion to perform.

It is a fact that for one hundred years no successful Cæsarean section was performed in the Vienna and Paris hospitals; but what ought we to expect when the natural death-rate at the time was between five and ten per cent? Dr. Harris has shown us that under favorable circumstances between seventy-five and seventy-six per cent. recover, and that all fatal cases result from conditions making the issue almost inevitable. Michælis reports cases in which the woman was operated upon with a razor, another in which the patient was dying, and still another in which the patient was actually a corpse, and yet these are attributed to the natural mortality of the operation.

Porro's operation was at first adopted so widely because it was believed that the wound would, of necessity, gape in the Cæsarean operation. Sänger, however, disproved this, and taught us the conditions of success, reporting four cases without a death. A recent American

operator gave as his reason for choosing Sänger's method, in place of laparo-elytrotomy, for which his case was best adapted, that he did not wish to burden this latter with another death.

These various methods are not rivals, but clearly fulfil different indications. The Cæsarean method must have the preference in favorable cases taken early. The Porro method is best adapted to cases in which the uterus is exhausted, and the presumption is that degenerative changes have occurred. Laparo-elytrotomy is the operation for cases in which, with the head at the brim, the uterus has retracted above it.

Dr. Wilson, of Baltimore, stated that he had not performed craniotomy for thirty years, and agreed with Dr. Lusk as to the various fields he had indicated for these different methods.

Lawson Tait spoke in favor of the Porro method, and thinks we are bound to protect the woman from the future dangers from her two and a-half inch pelvis. Half of the children die anyhow, so why should we argue against an operation which prevents childbearing? Craniotomy too, is just as fatal as the Cæsareon section.

Dr. T. M. Madden, of Dublin, speaking from an experience of twenty years, in the largest lying-in hospital in Great Britain, said that he had never performed craniotomy, and he looked at the question from a moral standpoint; the balance of life should not be poised on the hand of the physician as here. It is but too often as Simpson has said, "Cold steel for the child, and mercury for the mother," to combat the peritonitis.

Dr. T. A. Emmet, of New York, read a paper on "Certain moot Points in Gynecology," and was immediately followed by Dr. Grailey Hewitt on "The Early History and Etiology of Uterine Flexures and Displacements."

Dr. Emmet made a very clear, succinct statement of his views, declaring that versions are but symptoms, and stenosis is a matter of little importance. The relief following the use of a pessary is not due to the correction of a displacement, but to the fact that it takes up the slack in the broad ligaments, and supports the blood-vessels, relieving the congestion. The common symptom of irritable bladder is not due, as so often supposed, to a prolapse of the uterus, but to the traction by the cervix on the utero-vesical folds, and thus, by lifting the cervix with a pessary, relief is obtained. Flexure is often merely an individual habit. Dr. Emmet has observed the most extreme stenoses without accompanying symptoms.

Dr. Emmet recorded a case seen lately, in which the cervix had been divulsed two years ago, and she is now under his treatment for a pelvic peritonitis, from which she has suffered ever since, and he has observed a rapidly growing epithelioma.

If there is one thing his experience in the past fifteen years has taught him, it is this constant association between lacerated cervix and epithelioma. Pelvic inflammation is best treated by small doses of ergot and the hot water douche. Dr. Emmet has not owned a sound for three years and possesses no uterine probe. An analysis of the cases under treatment before and after giving up intrauterine applications, shows a most remarkable difference, in favor of the latter, in the average number of days the cases remained under treatment.

Dr. W. T. Lusk read a paper on Thursday afternoon on "The Proper Moment for the Performance of Gastrotomy in Abdominal Pregnancy." This was followed by Dr. T. H. Aveling on "A Case of Extrauterine Gestation Arrested by Electricity."

Dr. Michael Beverley reported twenty cases of Emmet's operation for "Laceration of the Cervix;" and three for "Procidentia Uteri." The record was an admirable one, showing the clearest insight, on the part of Dr. Beverley, into the etiological factors concerned. In the discussion following, Dr. Kelly pointed out that lacerated cervices were not any more frequent in America than in England and Germany, the sole difference was one of *names* only; all those cases which abroad were labelled and treated as *erosions*, were almost without an exception *lacerations*. And no better illustration of this could be found than in the excellent colored picture in Ruge and Veit's "Erosio Uteri und beginnender Krebs," published in the *Zeitschrift für Gynäkologie*. Here the pictures so generally copied as types of erosions, were typical examples of as many grades of lacerations, the first two requiring puncture and packing or the douche to soften them down, bring the lips together and, by the rational plastic operation, complete the cure. Dr. Kelly also drew attention to the three essential points to be borne in mind in all operations practised on the vagina with a view of retaining the pelvic viscera.

The Section closed with a paper read on Friday morning by Dr. Thomas Savage, of Birmingham, on "Removal of the Uterine Appendages," followed by a timely protest by Dr. Moore Madden upon the same subject. Dr. Savage expressed himself well, and to the satisfaction of the members, who concurred in his views, almost without an exception. The discussion following was of unusual interest, and was participated in by Dr. G. Bantock, of London; Dr. E. T. Davies and Dr. Elder, of Nottingham; Dr. Wilson, of Baltimore; Dr. Imlach, of Liverpool; Dr. Gordon, of Maine; Dr. Gill Wylie, of New York; Mr. Lawson Tait, of Birmingham; and Dr. H. A. Kelly, of Philadelphia. Dr. Wylie's remarks added especial interest, as he detailed some of his good work in dealing with difficult tubal and ovarian cases in New York.

On Thursday Dr. G. Ranney, of Michigan, read an interesting paper upon the treatment of mastitis by compression.

It is impossible to conclude without acknowledging the constant kindness and courtesy the distinguished President and members of the Society showed their visitors, which only ended with a handsome lunch given by Dr. Meadows at the Grand Hotel at the close of the final meeting. Howard A. Kelly, M.D.

Birmingham, August 20, 1886.

CATGUT SUTURES FOR OPERATIONS UPON THE LACERATED CERVIX AND ELSEWHERE.

To the Editor of The Medical News,

Sir: Dr. Robert T. Morris makes a little hit at Dr. Sutton in your issue of July 17th, and makes at the same time a rather sweeping assertion about gynecologists generally which I cannot permit to go abroad unrefuted. Undoubtedly the surgeons who "insert sutures of antiseptically prepared catgut into the lacerated cervix, sprinkle the surface with iodoform, and do not disturb

the womb with frequent washings," are doing the proper thing, and a very clever thing too. But gynecologists, especially abroad, do the same, and he should not make so unqualified a statement representing this as the invariable habit of general surgeons, and only of surgeons, and that gynecologists are absolutely in the dark regarding these simple methods of treatment. Let me say that for many years, certainly five or six years, I have pursued the course he speaks of, and which Dr. Sutton now advocates, never using washes or injections in the after-treatment of uterine or vaginal operations. I have treated all such wounds by a strictly dry antiseptic method—that is, a let-alone method; after an operation antiseptically performed I have dusted the surface with iodoform, covered it with antiseptic cotton or gauze, and so left it until, when silk was used, it was time to remove the sutures, or when catgut was used, I had reason to change the dressing perhaps on the fourth or fifth day, perhaps not until I desired to examine the part. Cleansing of the surface by vaginal injections, washes, etc., I have never insisted upon, and strictly forbidden since antisepsis has been taught.

During the past year I have used catgut to the exclusion of every other material for all operations upon the uterus, vagina, and perineum, and, in part, even for the closing of abdominal incisions. For the past ten years it has been my wish to use it, knowing that theoretically it was the correct thing; but the catgut, as offered for sale, prepared in various ways, was neither a convenient nor agreeable material for use. I always had it on hand, often attempted to use it, but finally gave it up in disgust. I have tried whatever has been recommended: in early years I clung to the silver wire, then to silk, which I have used for the last four or five years, in preference to silkworm gut, kangaroo tail, or whale tendon, which I have tried without discovering any great advantages; I have used silk exclusively, giving other material a fair trial; but since I have seen the catgut prepared with corrosive sublimate, glycerine, and alcohol, I have used nothing else, and I fully agree with the high estimate which Dr. Morris places upon this material, and which is, notwithstanding his assertion, well known to gynecologists, and used almost exclusively by some.

Catgut so prepared is undoubtedly superior to any other material: *first*, it is very strong, almost as strong as silver; *second*, it is less irritating than any other material; *third*, it is as convenient and agreeable to handle as silk; and *fourth*, it is self-removing, and can be timed with almost the exactness of a fuse; by selecting the proper size we can control the time during which it shall bind the parts. It is of the greatest advantage to use a material so nearly allied to the tissues which it holds, and which we are not obliged to watch, lest we run the risk of leaving a suture, and thus keeping an irritant, a foreign body in the parts.

The dry method, which I have for many years adopted for the dressing of recently united parts, is the only one which is really antiseptic, if not aseptic, and this is the only proper method of dressing in the after-treatment after antiseptic operations. Some gynecologists, both in France and Germany, use catgut freely; but I believe no one has used it so exclusively as I have, relying upon it for perineal, and even abdominal operations.

Truly yours,

ST. LOUIS, August, 1886. GEORGE J. ENGELMANN.

NEWS ITEMS.

AMERICAN SOCIAL SCIENCE ASSOCIATION.—The General Meeting of this Association for 1886 will be held at Saratoga, N. Y., from September 6th to 10th, inclusive, opening at 8 P. M., September 6th, with an address by the President, Carroll D. Wright, of Boston. The Department of Education will meet on Tuesday, September 7th; the Health Department on Wednesday, September 8th; the Department of Jurisprudence on Thursday, September 9th; and the Social Economy Department on Friday, September 10th. Papers on scientific subjects will be read by Drs. Grace Peckham, Holbrook Curtis, Valentine Mott, Wallace Wood, T. Munson Coan, all of New York.

THE PASTEUR EXHIBIT AT THE EXPOSITION OF URBAN HYGIENE AT PARIS.—Men and women gape wonderstruck before a table loaded with a hundred or so glass mattrasses in which Pasteur works his *bouillons*. A large sign cautions the public, "Do not touch: very dangerous;" and the concoctions of charbon, hydrophobia, typhoid, and other uncanny microbes are severely left alone. The cages in which the unfortunate rabbits are kept are only seen in photographs, but rabid marrow and dog-rolling cages are there in reality. The latter are made of strong galvanized iron, and provided with rollers, a hook on top, and a perforated bottom. In each cage remained the tin dish used for the prisoner's food; the metal's edges are deeply indented and torn in some places by the teeth of the late occupants, showing but too vividly the horrible disease that carried them off.

PASTEUR'S METHOD.—In the House of Commons lately Charles Thomson Ritchie, President of the Local Government Board, stated that the committee appointed by the government to examine into the Pasteur method of inoculation for rabies was fully satisfied that the French savant's treatment for hydrophobia was effective.

INTERNATIONAL STATISTICS OF THE INSANE.—The conference of the various committees appointed by scientific bodies and eminent alienists, to agree upon a uniform classification of mental diseases, in order to secure the best basis of International statistics of the insane, in coöperation with the International Committee appointed at the Antwerp Congress, held by the Belgian Society of Mental Medicine last autumn, will be held at Saratoga, N. Y., on September 8, 1886, at 10 o'clock, A.M. Dr. Pliny Earle has been invited to preside.

COLDWATER SANITARY CONVENTION.—The time for holding the Sanitary Convention at Coldwater, under the auspices of the Michigan State Board of Health, has been changed from September 23 and 24, to September 9 and 10, 1886.

THE ENGLISH CONGRESS OF HYGIENE will be held at York in September, under the presidency of Sir Spencer Wells.

THE FIFTY-NINTH REUNION OF GERMAN NATURALISTS AND PHYSICIANS will be held in Berlin from the 18th to the 24th of September. A cordial invitation has been isued to those interested in all countries.

HONORS TO MEDICAL MEN.—The Queen has recently conferred the honor of knighthood upon the following gentlemen amongst others: Mr. John Tomes, F.R.C.S.; Mr. Douglas Maclagan, M.D.; Surgeon-General Thomas Longmore, C.B., Professor of Military Surgery at Netley; and Mr. Edward Sieveking, M.D., Physician Extraordinary to the Queen. On the 2d inst., amongst the distinguished colonial visitors who were invested with various Orders, the following were made Companions of the Order of the Indian Empire: George Watt, M.D., and John W. Tyler, M.D.

SUBAQUEOUS VEGETATION.—An interesting discovery has been made in Switzerland of a bright green moss, growing on calcareous rock two hundred feet below the surface of Lake Leman. No other moss has been known so far under water; and how chlorophyl, the green coloring-matter, could have been so richly developed in a place so remote from the light, is a problem; probably the extraordinary clearness of the water enabling the sun's rays to penetrate to a great depth.

THE SCIENTIFIC SPIRIT.—Let those who think they know, without ever having looked to see, review their supposed knowledge and cast their thoughts over again; and if, in the particulars, they find they have mistaken words and fancies for realities, and accepted the dicta of pretenders instead of the evidence of observed facts, let them correct the record, and acknowledge the truth as it is in nature. Moreover, let them remember that he who propagates a delusion, and he who connives at one when already existing, both alike tamper with the truth, and that we must neither lead nor leave men to mistake falsehood for truth. Not to undeceive is to deceive.—DR. T. WHARTON JONES.

THE USE OF GAS COOKING-STOVES is increasing in Great Britain. Many of the Scottish gas companies now let out the stoves at a cheap rate. Dr. Stevenson Macadam speaking of gas-cooking in its sanitary aspects, says: "The wholesomeness of the meat cooked in the gas-stoves must be regarded as beyond doubt. Gas-cooked meat will be found to be more juicy and palatable, and yet free from those alkaloidal bodies produced during the confined cooking of meat, which are more or less hurtful, and even poisonous." A joint cooked in a gas-oven weighs heavier than the same joint cooked in a coal-oven, because the juices are more perfectly preserved in it.

MEDICAL STUDENTS IN SWISS UNIVERSITIES.—The number of medical students in Switzerland appears to be increasing. During the present summer session the total is 675, including 81 women, who are admitted in Berne, Geneva, Zurich, and the preparatory school of Lausanne, but not in Basle. In Berne there are no less than 40 female students; some of the assistants' posts are filled by women. It is remarked that their exercises, or degree theses, are usually selected from theoretical subjects—such as anatomy, physiology, pathological anatomy, and pharmacology—rather than from practical medicine and surgery. The increase in the number of sudents is due almost entirely to an accession from Switzerland itself, the number of foreigners (192) being much the same as in former years. Of the 81 female students, only 10 are of Swiss nationality.

NOTES AND QUERIES.

GUTTA-PERCHA FOR MARKING THERMOMETERS, URINOMETERS, ETC.

For marking thermometers and urinometers that have become indistinct from wear and washing in the one case, and the action of urine in the other, I take an old hard-rubber thermometer case, hold one end in a gas flame until it ignites, and then rub the burning end over the figures, running all the grooves full of melted gutta-percha. After waiting a few minutes for it to cool, I take a sharp knife and cut off the surplus rubber, and leave the grooves filled with black, shiny, insoluble gutta-percha. To mark bone-handled instruments, I scratch, or cut, whatever mark I wish to have on them, and use the gutta-percha as described above. An old gutta-percha button answers the same purpose as a hard-rubber thermometer case.

Resident Physician
Jefferson Medical College Hospital.

Philadelphia, August 31, 1886.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT, U. S. ARMY, FROM AUGUST 24 TO AUGUST 30, 1886.

WOODHULL, A. A., *Major and Surgeon.*—Granted leave of absence for fourteen days, to take effect on or about September 1, 1886.—*S. O. 197, A. G. O.*, August 25, 1886.

TAYLOR, M. K., *Major and Surgeon.*—Leave extended one month.—*S. O. 195, A. G. O.*, August 23, 1886.

LAUDERDALE, J. V., *Captain and Assistant Surgeon.*—Granted leave of absence for two months, with permission to apply for one month's extension, when his services can be spared.—*S. O. 195, A. G. O.*, August 23, 1886.

GANDY, CHAS. M., *First Lieutenant and Assistant Surgeon.*—On expiration of his present leave of absence, relieved from duty in the Department of the East and assigned to duty in the Department of Texas.—*S. O. 195, A. G. O.*, August 23, 1886.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY, FOR THE WEEK ENDING AUGUST 28, 1886.

CLARK, JOHN H., *Medical Inspector.*—Ordered to special duty, Portsmouth, N. H., and Widow's Island.

KINDLEBERGER, D., *Medical Inspector.*—Ordered to Hospital, Washington, D. C., October 1, 1886.

GIHON, A. L., *Medical Director.*—Ordered to Hospital, Mare Island, Cal., October 15, 1886.

ROBINSON, SOMERSET, *Medical Inspector.*—Detached from Hospital, Mare Island, Cal., October 15, 1886, and wait orders.

SPEAR, J. C., *Medical Inspector.*—Ordered to Naval Laboratory, New York, September 28, 1886.

BLOODGOOD, DELEVAN, *Medical Director.*—Ordered to Hospital, Norfolk, Va., September 29, 1886.

TAYLOR, J. Y., *Medical Director.*—Ordered to Naval Laboratory, New York, September 29, 1886.

DEAN, R. C., *Medical Director.*—Detached from Naval Hospital, New York, and wait orders.

SIMON, W. J., *Surgeon.*—Detached from U. S. S. "Constellation," and ordered to special duty at Naval Academy, Annapolis, Md.

HENRY, C. P., *Assistant Surgeon.*—Ordered to Hospital, Philadelphia, Pa.

FITTS, H. B., *Passed Assistant Surgeon.*—Detached from Hospital, Philadelphia, Pa., and wait orders.

STONE, *Assistant Surgeon.*—Ordered to Receiving Ship "New Hampshire."

ORIGINAL ARTICLES.

SUBCUTANEOUS DIVISION OF URETHRAL STRICTURE.[1]

BY C. H. MASTIN, M.D.,
OF MOBILE, ALABAMA.

ORGANIC urethral stricture becomes sometimes so difficult and so obstinate an affection to treat that we are forced to resort to other than the usual methods for its relief. Such being the case, it is not surprising to find that, from the earliest times, dangerous and difficult operations have been introduced for its cure, or rather for its immediate relief: among which are incisions made from the outside, through the integument and urethral wall, dividing all the diseased structures, and leaving the parts gradually to reunite. Such operations may all be embraced in the one general term "External Urethrotomy."

As far back as we have any recorded history of surgery, we find the ancient surgeons, like ourselves, encountering difficulties in the treatment of urethral stricture, and oftentimes unable to gain an entrance into the bladder through the natural channel. Hence, they were forced to resort to the use of the knife, by which incisions were made into and through the urethral walls. Celsus was evidently familiar with such an operation, for in Book vii., Chapter xxvi. of his writings, we find this passage:

"In suppression of urine, if the urethra is stopped by a stone, the prepuce must be drawn out as much as possible, and, the glans being covered, it must be tied by a thread; then, on one side, a longitudinal incision must be made into the penis, and after this the prepuce is let go; for by this means the sound part of the skin covers the incision in the penis, and the urine will be discharged in the natural way."

It is very evident that he certainly intended to speak of *retention*, and not *suppression* of urine, and that the incision was made in the urethra and not into the body of the penis. A natural inference to be drawn from this quotation is that, if Celsus advised opening the urethra to get rid of an impacted stone which was obstructing the flow of urine, he evidently would have advised a similar operation in a case of retention caused by any other obstruction, as, for example, stricture of the canal. Still later than the time of Celsus, we read in the writings of Rhazes in the tenth century, a clear description of such an operation having been done for obstruction of the urethra. Again, Avicenna, who wrote in the eleventh century, mentions puncture of the urethra through the perineum for the relief of retention of urine. These operations appear to have been intended solely to give exit to retained urine, but with no intention or proposed plan of curing the disease which caused or produced the obstruction; the object of the ancients being more the relief of the immediate symptoms than an endeavor to eradicate the disease.

The first reliable mention of an operation of which we have any positive knowledge, which was performed for the cure of stricture, and not entirely for the relief of retention, is the one recorded by Richard Wiseman, in his work entitled *The Ill Consequences of Gonorrhœa*. Here he speaks of having witnessed, in the year 1652, an operation done by Mr. Edward Molins, "which," says Wiseman, "consisted of an incision into the urethra near the neck of the bladder, for retention of urine; that the knife did not readily divide it, for it was as hard as a gristle; the urethra being opened, the urine gushed out, and the wound remained fistulous." In this operation, if we fully understand Wiseman's description, the incision was made into the urethra posterior to the obstruction, and subsequently the incision was carried through the coarctation to its anterior face, a very similar operation to the "boutonnière," a proceeding of which we shall have occasion to speak more at length in the course of this paper.

Again, in the latter part of the same century, we find Soligen performing similar operations, once at Livourne, and again at the Hague. Then we hear of an operation, which was designated "la boutonnière," being done in 1687 by François Tolet, for the relief of retention, but not for the cure of stricture; and he tells us that it was an operation much in vogue "by men of great skill and reputation," and employed by them only in cases of great emergency.

Then, François Colot follows him, operating in 1690 for the cure of impassable stricture complicated with perineal and scrotal fistulæ. From that date onward we find, scattered here and there through the early literature of the profession, only references to the subject, until the year 1730, when Ledran operated upon "a case of organic impassable stricture;" this operation he did at two sittings, and after the following manner: The first day, the perineum was opened down to the urethra, and on the succeeding day he opened into the canal upon the anterior face of the stricture, through which, after gradual dilatation for five days, he passed a bougie on into the bladder; when this had been accomplished, he "slit up the urethra as far as the neck of the bladder." Gradual dilatation was then resorted to, by which the entire length of the urethra was stretched open, and the patient is said to have gotten well.

About the same date, J. L. Petit, on numerous occasions, appears to have performed similar operations for retention of urine, and in some cases he divided the stricture at the same time, with the evident in-

[1] Read before the American Surgical Association, May, 1886.

tention of curing the obstruction. Petit relates a case where he performed the operation for the cure of a stricture through which it was impossible to pass an instrument, although there was no retention of urine, and no fistulæ through which urine could find its way. He cut through the urethra at the face of the stricture, upon a grooved sound introduced down the canal to the seat of obstruction, after which he forced a trocar through the obstruction and into the bladder, following the supposed course of the urethra. He then slit up with a bistoury the strictured portion, tied in a catheter, and left the wound to heal by granulation, which it did in about a month or longer time, and the patient is reported as having been entirely cured. This was probably the first case in which a "sonde à demeure," or retained catheter, was ever used. Petit subsequently resorted to a similar operation in a number of cases, and states that, whenever he has performed "la boutonnière" (as he termed it) for retention of urine, his patients always "regained the freedom of the canal when he comprehended the obstacle itself in the incision." But he is very careful to remark that "the boutonnière is to be shunned whenever the introduction of a sound is practicable."

In 1750, twenty years after the operations of Ledran, Mr. Sharp, of England, described an operation very similar to his, "by cutting in *perinæo* if possible upon a staff," and recommended its performance;[1] but, in 1782, we find him condemning it in no measured terms, and advocating in its stead the suprapubic operation for relief of retained urine, as one less to be feared, and less serious in its results.[2] Only six years after this date—*i. e.*, in 1788—John Hunter comes to the front, and not only advises but urges the operation as the proper one for the cure of strictures complicated with perineal fistulæ; he himself having performed, in 1783, an operation in which he cut upon a staff introduced down to the stricture, and exposed the face of the obstruction, which was subsequently dilated so that the staff was with difficulty passed on into the bladder. This was neither new nor original with Hunter, for in the year 1738 both Astruc and Daran had described the operation as done by Hunter, and again in 1748 called the attention of surgeons to the method; but they both opposed and advised against its performance. In 1786 both Chopart and Desault performed the operation in various ways, but the mortality proved so great, and they denounced it in such violent terms that very few surgeons could be found who were willing to attempt it. Desault writes:

"The operation known under the name of 'la boutonnière,' though apparently better adapted to the nature of the disease, is, almost always, either useless or dangerous. It is useless if the surgeon has been able to pass a grooved director for the purpose of operating, because in such a case he might just as well introduce a hollow sound. It is dangerous if the surgeon has no director to guide him, for then he makes his incisions at hazard, may miss the canal, and divide parts, the lesion of which is followed by more or less serious accidents."

[1] "A Critical Inquiry," London, 1850.

[2] A Treatise on the Operations of Surgery, etc., by Samuel Sharpe, F.R.S., etc. Tenth edition. London, 1782. Chapter xv. pages 77, 78.

Chopart having had no success with the operation, became bitter in his denunciations of the procedure; and the failures, together with the great mortality attending it, about the close of the last century, threw it into such disrepute, that very few surgeons could be induced to perform it. Mr. Sharp, of England, then condemned it, and very soon it fell into disuse in France, and was not again practised in England until about the year 1807, at which time Sir Charles Bell called attention to it as an operation peculiarly adapted to, and required in those cases of aggravated stricture of the urethra complicated by perineal fistulæ: still the operation did not receive favor in England, and we hear little or nothing more of it until the year 1817, when it was revived and introduced into America by the late Dr. Alexander H. Stevens, of New York, who then operated successfully upon a case of stricture by this method after all other means of relief had failed. Then Dr. Jameson, of Baltimore, began to operate in 1820, and by the end of the year 1823 he had performed ten operations without a single death. This remarkable success with a hitherto unsuccessful operation naturally directed the attention of American surgeons to the method, and it was not long before it became popular in New York and other Eastern cities. Dr. D. S. Rogers, of New York, also began the operation in 1823, and very soon laid before the profession the report of twelve operations, all successful. By the year 1843 Warren, of Boston, March, of Albany, Hoffman, Post, Watson, and Buck, of New York, with many other American surgeons, had, by large numbers of successful cases, all done without the use of a conductor, so fully established the propriety of the operation, that it at once became an accepted operation on this side of the Atlantic.

Carefully examining the reports of these cases, we find they were all performed after the method of the "old boutonnière;" that is to say, without a conductor, which goes to prove they were cases impassable to instruments. So, before we investigate the subject further, it may not be out of place to show what is meant by that term, and then analyze the methods which come under that general description.

This operation has been performed in so many ways that we are at a loss to understand the exact idea which the old authors wished to convey when they used the term "la boutonnière." The most explicit description which we have been able to find, is the one given by Desault in his treatise upon the diseases of the urinary organs; this is, to my mind, most clearly evident that the operation was performed in three ways: *First*, upon a conducting staff which was passed through the stricture and on into the bladder, upon the groove of which conductor the incision was made. *Secondly*, where a staff was passed down the urethra until it reached the anterior face of the stricture, and the urethra opened upon the point of the staff, after which the stricture, together with the integuments, were all laid open by the knife upon a director which was introduced through the stricture *from its distal* opening. *Thirdly*, a staff was passed down to the stricture, and the urethra opened in the membranous portion posterior

to the obstruction, through which opening a grooved director was passed *from the posterior face* of the obstruction forward through the stricture until it came in contact, or nearly so, with the end of the staff as it rested upon the anterior face of the coarctation; then a knife was pushed along the groove of the director from behind forward, and the entire stricture, together with wall of urethra and integuments, all ripped open: this last method is the one usual with French surgeons. This completes a running epitome of the operation from its early history, to the year 1849, when Mr. Syme, of Edinburgh, called the attention of the profession to "A New Operation for the Cure of Urethral Stricture:" a method which he had devised, and which consisted in passing a special staff through the stricture, then opening the urethra behind the coarctation, upon the small grooved director attached to the staff; in this groove he passed a sharp, narrow-bladed knife forward through stricture, integuments, and all, laying the urethra freely open. It is, however, scarcely necessary to consume time by a long description of the method of the Scotch surgeon, or a detail of his cases, for I presume all are perfectly familiar with it.

It may not be uninteresting, however, to show what were the conclusions which he proposed to draw from his method; and it will serve my purpose better if I quote his own language on this point—they are as follows:

"1st. That there is no stricture truly impermeable, and that, with time and care in every case, an instrument may be passed through it, and serve as a guide for the knife.

"2d. That all strictures which cannot be remedied by simple dilatation, admit of effectual relief only through a free division of the contracted part of the canal.

"3d. That this object can be obtained with certainty and safety only by an external incision in a line corresponding with the raphé of the perineum upon a grooved director passed through the stricture.

"4th. That the only after-treatment required is the introduction of a catheter during forty-eight hours, with the subsequent use of a full-sized bougie at distant intervals.

"5th. That the operation, if properly performed, is free from any risk whatever of hemorrhage, extravasation of urine, or fistulous opening."

I shall examine these conclusions and see how far they may be fully received; whether or not, in the first place, the proceeding is entitled to be considered "a new operation;" how far, if in any particular, it differs from one of the varieties of "la boutonnière;" and, more important than all, whether it is free from danger. That it is not a new operation has been clearly proved by the description of the boutonnière by Desault. In his first division, he shows that the staff was passed through the stricture and the coarctation cut upon the groove of the same; in his third division, that the urethra was opened posterior to the contraction, just as Mr. Syme described it, a director passed from behind forward, and the stricture cut from its posterior to its anterior boundary. The director of Desault was passed from behind, whilst that of Mr. Syme was introduced from the front; this is the non-essential difference in the two operations, one of no consequence, since the stricture, integuments and all, were laid open and left to granulate after both operations.

Mr. Syme has assumed the non-existence of impermeable stricture, and says:

"There is nothing of more consequence in the treatment of stricture than the knowledge of the fact that this alleged impermeability has no real existence except in those cases where the urethra has been divided by violence and allowed to cicatrize with obliteration of the passage beyond the opening at the seat of injury. It is obvious, indeed, that if the urine is permitted to pass, no matter how small a stream, or even by drops there must be room for the introduction of the instrument, if it be sufficiently small and properly guided."

Even this assertion is not new, since Mr. Liston had, in 1835, enunciated the same opinion, as shown by this language—"there are no strictures impassable that I have ever seen, for where any water comes away, you can, by patience and perseverance, get a catheter through sooner or later." Still these assertions have not been proved, since we find in Mr. Syme's own work two instances in which he acknowledges that he was unable to pass his special staff, and consequently he was forced to open the urethra anterior to the stricture and then cut through the same, as in Desault's description of his second division of la boutonnière. Mr. Liston also has been repeatedly foiled in his attempts to introduce a catheter through an ordinary stricture, and was obliged to have recourse to an operation of tapping the bladder both above the pubis and also through the rectum. Yet Mr. Syme asserts that he has never been called upon to perform his operation for impermeable stricture, and simply because he had never met such a case. He makes permeability an indispensable prerequisite to the performance of external division, and does so upon the ground of the "*danger, uncertainty, and difficulty*" which, he asserts, must attend all operations done in the perineum in search of the urethra, without a guide. His own assertions are conclusive evidence that there are impermeable strictures, even if we had no better authority; but upon this point the united experience of almost all surgeons goes to show and to prove that there are cases of stricture oftentimes met with which are impassable to instruments yet not absolutely impermeable to urine.

2. His second conclusion is far from being sustained, since there are too many well-attested cures of resilient stricture—strictures which have proved rebellious to dilatation—which have been thoroughly relieved and permanently cured by the simpler operation of internal urethrotomy; thus sustaining the well-established fact that when a stricture is not impassable to instruments, external division is contraindicated.

3. If we can rely upon the testimony of Mr. Lizars—and his assertions have not been refuted—Mr. Syme's own cases were not with certainty and safety relieved. Mr. Lizars conclusively showed that the statements of Mr. Syme were not to be relied upon, since his cases had not been fairly or even correctly reported by himself, and that a large num-

ber of his operations proved failures, since in many instances the patients were placed in a most terrible condition as the result of his method: profuse hemorrhage occurring in quite a number of them, and also extravasation of urine followed by extensive sloughing, terminating in numerous fistulæ. Mr. Syme himself acknowledges the dangers of the operation when he writes, giving the history of some "eighty or ninety cases," that "alarming symptoms were by no means rare, since every third or fourth patient suffered from rigors, vomiting, delirium, or suppression of urine."[1] Besides these troubles, he met with two fatal cases which he attributed to contact of the urine with the wound.

It is not the purpose of this paper to cast the least reflection upon the distinguished surgeon whose name has been so intimately associated with this operation, nor to condemn the operation of external section. I am writing its history, and desire simply to give the result of my investigations, and show what objections are sustained against it. It is certainly proved, that from the most remote times it has been considered a dangerous and difficult operation, and even in our own day, when surrounded by all the appliances of improved surgery, and encouraged by the success which has attended it, some of the best modern authorities pronounce it an operation not free from danger, but one which requires the most consummate skill for its successful execution.

The venerable, gifted, and distinguished founder of this Association, a man who made, and has left his impress indelibly stamped upon the surgery of the nineteenth century, used this forcible language when writing of the operation:

"The operation is by no means free from danger and requires the most consummate skill for its successful execution. None but a madman or a fool would attempt it unless he had the most profound knowledge of the anatomy of the parts, and a thorough acquaintance with the use of instruments. Of all operations of surgery, this is the least to be coveted."[2]

The operation has not been fully accepted in France, and was rejected by a commission of the French Academy which was appointed to sit in judgment upon it. Civiale, than whom no sounder authority in matters pertaining to genito-urinary surgery has lived, himself never performed it, although he was known frequently to have had resort to the old operation of "la boutonnière."

With all the objections brought to bear upon the various operations of external section, still we are, as I before stated, sometimes called upon to relieve a patient from retention of urine, caused by obstinate and impassable or impermeable stricture: and when that rare contingency does arise, and when milder measures have utterly failed, the urethra remaining absolutely impervious,—letting in no catheter, letting out no urine—then undoubtedly this condition will establish a necessity, a legitimate and imperative and urgent necessity, for our making an artificial vent for the discharge of the contents of the distended bladder.

This brings me to the consideration of the indications which render such an operation necessary.

Indications.—1st. The impossibility of passing a sound into the bladder through the urethral canal, when a firm organic contraction blocks up the urethra and proves rebellious to either dilatation or internal urethrotomy. Here we are imperatively called upon to relieve an over-distended bladder, else we find cystitis being developed, bladder walls becoming hypertrophied, ureters dilated, and kidneys disorganized. The nervous system, overwhelmed by the absorption of urea, cerebral symptoms speedily ensue, and the patient dies comatose. In such cases, the constitutional distress is urgent, and the demand for relief imperative; it then becomes dangerous to temporize with milder methods, and as a rational but *dernier ressort* we must perform an external section. But even in such cases it is not always necessary to do an operation through the perineum, or from without inward; for in some cases it is possible to cut down through the axis of the urethra into and through the stricture, although it may be impassable to the smallest instrument. Of this I speak advisedly, since I have myself done such an operation upon several occasions where I was not willing to subject the patients to the gravity of an external section. It is true the operations were exceedingly difficult, yet they were completed with perfect safety and relief to the patients.[1]

2d. Infiltration of urine resulting in abscess may necessitate an external section. I do not here refer to those sudden cases where from direct injury the urethra has been ruptured and infiltration is the consequence, but I allude to those cases where a tight stricture has existed for a length of time; where a periurethral abscess has resulted from a small opening in the urethra behind the stricture, and the gradual infiltration of urine has lighted up inflammation to a degree sufficient to form a circumscribed deposit of pus. In such cases it is necessary to open the abscess for the purpose of relieving the sufferings of the patient. To do this more effectually, it will be well to carry the incision still deeper, and lay open the urethra at the site of rupture, then carry the knife forward through the stricture to the point of a sound introduced down to the anterior face of the coarctation.

3d. The third indication *might* be placed where certain cases of old tight strictures complicated with urinary fistulæ through which a great part of the urine escapes at every act of micturition.

Many surgeons contend that here is a clear and unmistakable indication for an external section, but, unless in some exceptional cases, I cannot give my unqualified assent to the proposition, since experience has clearly shown that in almost all cases of urethral fistula, so soon as the lumen of the canal is fully restored, the fistula heals; and very soon thereafter, when the normal calibre of the urethra has become established, the innodular tissue which sur-

[1] Lancet, Aug. 21, 1858, p. 191.

[2] S. D. Gross, Diseases, Injuries, and Malformations of Urinary Organs. Second edition, 1855, page 801.

[1] For report of cases, see Richmond and Louisville Medical Journal, Sept. 1873, vol. xvi. page 285.

rounds the fistulous opening becomes absorbed. Such being true, I prefer an internal section as less dangerous and equally efficacious.

4th. The most important indication which may arise, is when the urethra has been ruptured by a violent blow, and when the effects of such injury are rapid and severe. In some of these cases serious results do not take place immediately after the injury; but in others, enormous extravasation of blood may occur immediately upon the reception of the injury —then retention takes place, and the whole cellular tissue becomes infiltrated with urine.

In such cases the operation of external section becomes an absolute necessity, not only for the purpose of evacuating extravasated blood and infiltrated urine, but for the immediate purpose of getting a catheter into the bladder; for it becomes an almost impossible matter to introduce an instrument *per vias naturales* when the urethra has been lacerated. If, however, a free incision is made through the perineum upon the point of a large sound, first passed carefully down the canal to the point of injury, then the sound can be carried into the bladder and the patient placed in comparative safety.

5th. Traumatic stricture—that is, where a stricture has been formed as the result of a direct injury done to the urethra; for example, where fractures of the pelvis have injured the urethra and blocked up with a dense deposit the perineal and ischio-rectal regions. It is very well known how intractable such strictures prove, and how difficult, in many cases, it is to introduce an instrument of even the smallest size into and through such coarctations. In these cases ordinary dilatation proves inefficient, and internal urethrotomy is often of little or no avail. Here, then, we have an evident and clear indication for external section, as the speediest method by which we can gain access to the bladder.

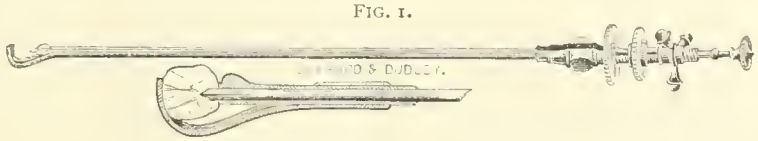
6th. A calculus impacted in the urethra behind a stricture, if large, may be an indication for opening the urethral canal. In some of these cases it is very difficult and oftentimes impossible to thread even the smallest filiform guide through the stricture for the purpose of conducting the staff of an internal urethrotome. In such cases, when an imperative necessity exists for the evacuation of an over-distended bladder, we have only the alternative of aspiration or external section remaining, and of the two, external section seems preferable, and should be done, thus removing the calculus and at the same time opening the stricture by an incision directed from behind forward through the coarctation. Even here an exception may arise should the calculus be small, in which event it is best to open the face of the stricture through the axis of the urethra, so as to expose the calculus, which can then be broken up and removed by the urethral brisepierre of Reliquet (Fig. 1), an ingenious instrument for this purpose, which this distinguished surgeon presented to the French Academy for its consideration in 1871.

7th. The next indication is when extravasation of urine has occurred from sudden rupture of the urethra, and in a short time extensive sloughing has taken place from infiltration of urine into the loose tissue of perineum, penis, scrotum, and groins. Here is an absolute necessity for making free incisions for the purpose of evacuating necrotic tissue together with pus and urine. In these cases it is well, if possible, to open the urethra at the site of stricture, so as to admit of the introduction of a catheter into the bladder. This is, however, not always possible when we come to consider the disorganized condition of the parts. In such cases nothing is left the surgeon save to meet the emergencies as they may arise.

8th. The last indication, if I may term it such, is the one in which Mr. Reginald Harrison advocates the combined operation of internal and external section. He advocates doing an external section immediately following an internal operation, and then keeping the bladder emptied through a large elastic drainage tube carried from the external opening into the bladder, and retained until the internal urethrotomy has healed. His reasons for this are, that patients, in his hands, have usually suffered from urethral fever after the first passage of urine, and that they do not have that trouble until the incision has been bathed by the urine in its passage along the canal. To avoid this complication, he advises doing the external section and draining the bladder. As it would necessarily increase the length of this paper for me to enter into a long detail of his special views upon this subject, I shall now close the indications for the operation by calling the attention of those who desire to know more of his paper to *The British Medical Journal*, of July 18, 1885.

In a given case, where an operation has been decided upon, the question arises as to what form of operation offers the best prospects of success, and which, under the circumstances, can be done with most ease to the surgeon. As for myself, I have found the operation as recommended by Mr. Syme, not only difficult to perform, but unsatisfactory in its results. An established maxim with surgeons has been that "a stricture being permeable to instruments, an external division is contraindicated." Mr. Syme, on the other hand, has reversed this, and made *permeability* an indispensable prerequisite to the performance of an external section. To this I cannot give my unqualified assent, since, in a very large experience, I have found that whenever I have been enabled to pass a guide through the stricture, I have almost always been enabled to perform a successful internal urethrotomy. Mr. Syme has un-

FIG. 1.



hesitatingly admitted the danger of his operation, and mentions hemorrhage as being often alarming. This trouble I have not encountered in my internal sections, and when I come to examine the records of several hundred cases in which I have done this operation I find only two instances in which hemorrhage has proved a troublesome factor, and both of these made good recoveries. In my operation for internal section I always carry my incisions through the upper portion or the roof of the urethra, as by so doing I am convinced the danger of hemorrhage is reduced to the minimum, because there are no arteries to cut, and the small venous bleeding soon ceases. On the other hand, extensive incisions made into the floor of the urethra and through the integument are done in the line of important structures, and vessels of considerable size, which, if wounded, give rise to profuse hemorrhage, and not infrequently serious consequences.

Again, in tight strictures it is extremely difficult to carry the small probe-like director (Fig. 2) from the meatus down the urethra and through the stricture; especially is it difficult to do so if there be false passages in the urethra, or within the stricture itself, and even if there be none already formed it is a very easy matter to make them. Hence it is that I should prefer to select the modification of this operation as proposed and introduced to the profession by my friend Dr. Gouley, of New York.

The main points in his operation consist in the manipulation of a delicate whalebone guide through the stricture, upon which guide he threads his tunnelled sound (Fig. 3) and passes it down to the anterior face of the coarctation; after which he opens the urethra from the outside upon the groove of the sound just in front of the stricture. This being accomplished, he searches for the whalebone guide, which then serves to conduct a very delicate, narrow-bladed knife (Fig. 4) into and through the obstruction; then the whalebone guide is removed and its place supplied by a delicate probe director (Fig. 5), which is pushed on into the bladder, and then the urethra, superficial fascia, and integuments are freely opened. His first incision is made directly in the median line of the perineum from the base of the scrotum to within half an inch of the margin of the anus, and is usually one to one and a half inches in length.

In opening the stricture he directs that the edge of the knife be held downward, and that the coarctation shall be freely divided, taking care to carry the incision into the uncontracted canal about half

Fig. 2.

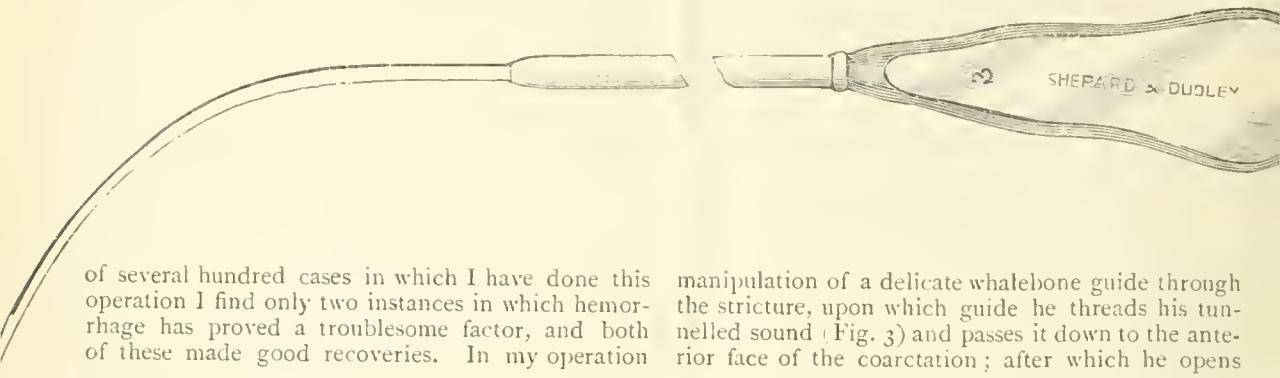


Fig. 3.

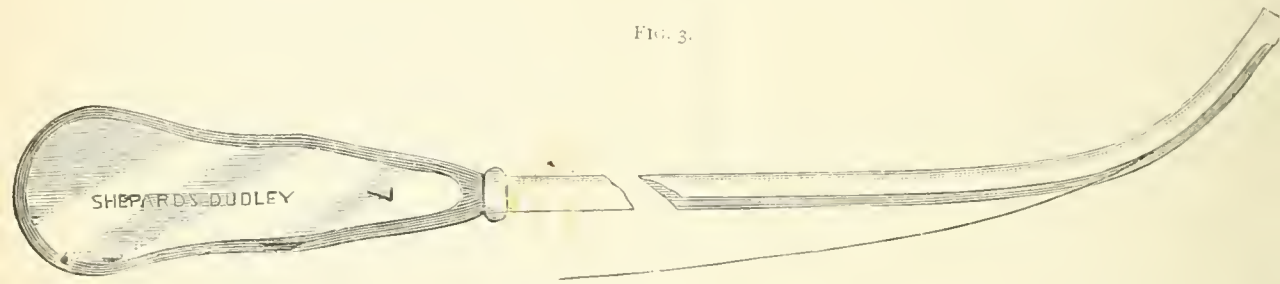

Fig. 4

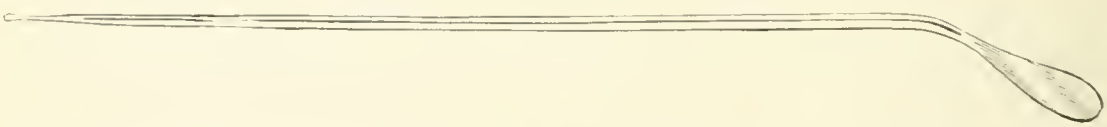
Fig. 5



an inch posteriorly. The case is then left to nature, and the urethra and the wound to the unobstructed passage of urine. The objections to Dr. Gouley's method are, the large size of the external incision, and the length of time required for the wound to granulate and heal. His incision through the stricture being made in the floor of the urethra endangers bloodvessels of importance, which become difficult of ligation if cut. The wound left to granulate is liable to the formation of numerous fistules, and a long time elapses before the patient is well enough to resume his ordinary vocations.

In this connection, I may refer to the method of Mr. Wheelhouse, which is known as "the Leed's operation." It possesses some advantages over the other forms which have been mentioned, chiefly so, from the ease with which it is performed; but it has still the disadvantage of leaving an open wound in the perineum to heal by granulation, and consequently it is liable to the after-consequences of perineal fistula. Mr. Wheelhouse certainly deserves great credit for the very ingenious and practical manner in which he has planned his operation, and his procedure has the advantage of greatly increased precision over any other form with which I am acquainted. By it an operation which was hitherto one of the most difficult in surgery, has been rendered comparatively easy, and the published reports go to show that the results have been vastly more favorable than from any other method yet described.

This operation is done upon a special staff designed for the purpose, which instrument is fully grooved through the greater part, but not through the whole of its extent, the last half inch of the groove being stopped and terminating in a rounded button-like end (Fig. 6). The urethra is opened *in the groove of the staff, not upon the point;* in this way, certainly securing at least a quarter of an inch of healthy tube in advance of the stricture; the opening in the urethra being held apart by two pairs of fixation forceps, applied one on either side, and the upper angle held up by the button extremity of the staff hooked in it. This opens the urethra and fully exposes the face of the stricture, in which the opening is searched for with a probe-pointed director, which, when it enters the bladder, is turned down so that the groove faces toward the perineum. Then the knife is directed along the groove and the stricture is carefully and deliberately opened on its under surface, and the passage thus cleared. This being accomplished, the probe-gorget of Mr. Teale (Fig. 7) is passed into the bladder with its concavity looking toward the pubis, so as to receive the point of a catheter, which is now introduced along the urethra until it reaches the gorget, by which it is conducted into the bladder; the gorget is now removed and the catheter tied in to remain for three or four days. After the expiration of that length of time the catheter is removed, only to be reintroduced each day or every second day, so as to keep the urethra in a state of patency until the wound in the perineum has thoroughly healed. The operation is ingenious, and, as a form of "la boutonnière," it deserves to be recommended; still it has, to my mind, the disadvantage which attends all of these operations, viz., leaving an extensive wound in the perineum to heal by granulation, exposing the patient to the dangers of pyæmia, and the liability of urinary fistulæ as a sequence. A very interesting description of this operation is to be found in the *Brit. Med. Journ.*, June 24, 1876, from the pen of Mr. Wheelhouse himself.

The idea has prevailed that, when the external incision is not large and free, urinary infiltration will necessarily take place; but this is an erroneous conception like that which has existed in reference to cutting for stone. The urine, obeying the natural law of gravity, does not infiltrate and burrow under tissues when it has an open channel through which it can escape. So it is, whenever a stricture has been fully divided, the urine necessarily follows the course of the urethra.

(*To be concluded.*)

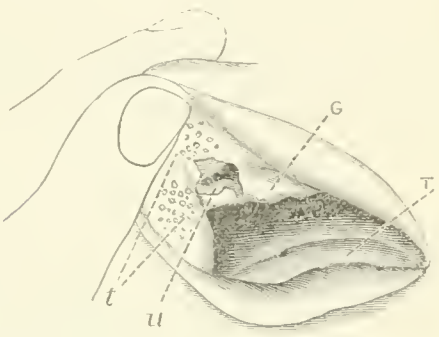
AN EXAMPLE OF DIRECT INFECTION OF TISSUE BY TUBERCLE.

BY J. SOLIS COHEN, M.D.,
OF PHILADELPHIA.

A CASE of tuberculosis pulmonum et laryngis now under my care has so well exemplified the direct transport of the infectious principle of tubercle from one surface to another that no excuse is necessary for placing it on record. A man forty-two years of age, who has led an exposed life on the Atlantic Coast of the Eastern States, but who claims that his family history has been good, is suffering with typical chronic tuberculosis of the lungs, larynx, and other organs. The larynx shows great infiltration of



Upper lip of tuberculous subject, showing direct infection. (From a drawing by Dr. Arthur W. Watson.)
T. Tongue.
g. Edentulous gum.
u. Tuberculous ulcer in gum and transition to lower portion of upper lip.
t. Tubercles further out in the lip, where it has lain in contact with the ulcer.

the epiglottis, greater infiltration of the periarytenoid and perisupra-arytenoid structures, with thickening in the anterior and middle portions of the ventricular bands, of the vocal bands, and most likely of subglottic tissues also which cannot be brought under illumination. Aphonia, long present, is due to infiltrating tumefaction preventing approximation of the vocal bands. No ulcerated points can be detected laryngoscopically. On the margin of the edentulous gum of the upper jaw of this patient, and extending across the sulcus between gum and upper lip, is a characteristic tuberculous ulceration, and on those portions of the lip which lie in contact therewith, are numerous points of recent nodular tubercular infiltration, evidently from direct infection. A somewhat similar example, in which the perisupra-arytenoid tissue became infected from a tuberculous ulcer on the epiglottis, is pictured in Fig. 115, p. 503, of the second edition of my treatise on *Diseases of the Throat and Nasal Passages*, New York, 1879.

ANASTOMOSIS OF RETINAL VEINS UPON THE OPTIC DISK.

BY B. ALEX. RANDALL, A.M., M.D.,
OPHTHALMIC AND AURAL SURGEON TO THE EPISCOPAL AND THE CHILDREN'S HOSPITALS, PHILADELPHIA.

THE comparative rarity of this form of anomalous arrangement leads me to place upon record the following case: W. H. S., aged thirty-five, employed in a hosiery mill, visited the eye clinic of the Episcopal Hospital in April because of pain in the eyes and head and dimness of vision, rapidly coming on when using the eyes in near work. The eyes were somewhat watery, the conjunctiva injected, and the anterior perforating veins large and tortuous. The vision was but $\frac{20}{XL}$ in each eye, less distinct in the left.

The ophthalmoscopic examination shows in the right eye a disk apparently large, nearly round, with a large shelving excavation extending to the outer margin, and a disturbed crescent of choroid down and out, with a large aberrant artery (lower temporal) emerging from beneath it. The upper veins enter the substance of the disk near the margin and are irregular in their arrangement; the upper artery emerges from the porus. A prominent tongue of tissue, arising from the centre of the disk and extending downward to the margin, almost hiding the ending of the lower vein to its temporal, and the origin of the lower artery to its nasal side, constitutes the most marked anomaly. It seems to blend with the thickened sheath of the vein at the lower disk margin. The eye shows low hypermetropic astigmatism, with considerable disturbance of the choroid and some tendency to accommodative spasm.

In the left eye the disk is of similar size and form, with a small and deep central excavation, into the outer portion of which most of the veins enter.

There is considerable choroidal disturbance at the outer margin, with pigment-heaping and absorption, the lower portion of the crescent seeming to be in a plane deeper-lying than the general choroidal level.[1] The lower artery arises near the lower nasal margin of the disk, the upper from the upper part of the porus. A large vein (upper nasal) enters the

[1] The cut is not strictly accurate as a portrait, but depicts faithfully the relations of the veins constituting the anomaly.

substance of the disk in the middle of the upper nasal quadrant. Connecting this with the adjacent vein which passes into the porus is a straight communicating vein about one-half as large as either of the vessels which it unites, and nearly at right angles to the course of each. Its relation to each vessel is unmistakable, and there is no neighboring vessel with which it might be confused. The general condition of the choroid is almost as bad as in the periphery of the other eye. The refraction is as in the other, less masked by spasm of the accommodation.

It may be noted that there is marked distortion of the nose to the left, but no other notable asymmetry or anomaly of the head.

1806 Chestnut Street.

MEDICAL PROGRESS.

The Absorption of Drugs from Lanolin Ointments.—In the *Vratch*, No 23, 1886, p. 421, Dr. P. V. Burjinsky describes the results of his experiments, carried out in Professor V. A. Manassein's clinic. The preparations of lanolin, used by the author, were quite pure (obtained either directly from Jaffé and Darmstäter, or from Professor A. W. Poehl's laboratory in St. Petersburg). The ointments were rubbed with the palm of the hand, under strong pressure, into the internal surface of the arm and forearm, the procedure lasting from fifteen to twenty minutes. Only fixed (non-volatile) and indifferent (non-caustic) substances of known chemical composition (such as ferrocyanide of potassium, hydrochlorate of quinine, sodium salicylate, and salicylic acid) were used. The question of cutaneous absorption was decided exclusively on the ground of the drugs passing in the urine. In seven of twelve experiments (in four with ferrocyanide of potassium, two with quinine, and one with sodium salicylate) the results were entirely negative; that is, not a trace of the drugs employed was discovered in the urine, the analysis being repeated hourly from six to eighteen times. In the remaining five (one with sodium salicylate and four with salicylic acid), there was obtained the well-known violet reaction with perchloride of iron; it appeared from one to four hours after the inunction. But the same reaction was obtained, also, two hours after the inunction of the same amount of an ointment made of salicylic acid and hog's lard. Having considered the results above given, Dr. Bürjinsky lays down the following propositions: 1. So far as penetration of drugs through the skin is concerned, lanolin seems to have no advantage whatever, comparatively, with other fats used as a basis for ointments. 2. Lanolin is a good constituent for ointments, since (*a*) it is a neutral fat not liable to become rancid; (*b*) it is easily miscible with glycerine fats and water; and (*c*) it gives delicate, fine ointments. In conlusion, the author draws attention that it is necessary to ascertain whether the process of preparation of cholesterin-fat gives security against any possibility of infection with anthrax.—*London Medical Record*, July 15, 1886.

Replantatio Dentis.—Grevers records the case of a fourteen-year old boy who fell from a height upon his face, whereby a first upper incisor tooth was completely removed from its alveolus. Then the alveolus was cleaned, the tooth disinfected, replaced with considerable pressure and resultant pain, and maintained in position by elastic slings attached to the neighboring teeth. In six weeks the tooth had regained its firm attachment and it was in no wise distinguishable from its fellows.—*Centralbl. f. d. med. Wiss.*, July 24, 1886.

Bichloride of Mercury and Tincture of Belladonna in Membranous Croup.—Dr. J. H. Jones writes as follows to the *New York Medical Journal* of August 21, 1886:

I have for some years been in the habit of treating this disease with a combination of corrosive sublimate and belladonna. These drugs are recommended for this complaint in almost every work on therapeutics, but I am not aware that they have ever been given conjointly. I have found that small doses of the bichloride (one-fiftieth of a grain), administered in conjunction with tincture of belladonna (two to five minims), every half hour for a child two years old, is a very successful method of dealing with this dangerous disease of childhood. The secret of its success is in its persistent administration, even when the symptoms are apparently most unfavorable. I have several times witnessed a happy termination to the disease when other practitioners with whom I was associated entertained scarcely a hope of recovery. It is advisable to commence the treatment by administering an emetic, so as to dislodge the already formed membrane. Probably much of the benefit derived from this mixed treatment is due to belladonna, and it is astonishing what large doses of this drug children can tolerate. During the progress of the disease the strength must be maintained by a liberally nutritious diet and stimulants, for I must say that when recovery takes place the patient is left very anæmic and weak. This is not very apparent while the medicine is being given, as every evidence of it is partially masked by the physiological effects of the belladonna.

The Diuretic Action of Watermelon.—In the course of a prolonged study of remedies used in Russia as diuretics, Popoff (*Vratch*, No. 4, 1886) finds that watermelon has been commended as an extremely cheap but effective substitute for grapes in the treatment of chronic congestion of the liver, chronic intestinal catarrh, etc. It is extensively used by the peasantry in Southern Russia (especially near the river Don, and in the Caucasian districts) in the form of the freshly expressed juice, as a diuretic draught in cases of dropsy, urogenital affections (especially gonorrhœa), etc. The author experimented with the inspissated fresh juice or syrup of the fruit, and with commercial melon-honey (*arbooznyi miod*). The diuretic action proved most striking; when animals received from 50 to 100 grammes of the syrup (with food) in twenty-four hours, the daily quantity of urine was three or four times greater than under ordinary conditions; again, on intravenous injection of the syrup "the urine for several minutes flowed in a stream from a canula tied into the ureter." On the subcutaneous injection of 0.4 to 0.7 gramme into frogs the syrup rapidly slows the cardiac action up to complete arrest in diastole, and produces prostration with loss of voluntary movements, while reflex action

and the excitability of the motor nerves and muscles remain intact. When very large doses are used, in the latest stages there is observed, also, a failure of reflexes and of nervo-muscular excitability, but the phenomenon is then undoubtedly nothing but an ordinary symptom of præmortal agony. In dogs the internal administration of 500 grammes at a time produces no effect except powerful diuresis. Intravenous injection of one to two grammes of the syrup causes an immediate increase in the secretion of the urine, the latter assuming a dark color and containing sugar. This increase lasts for ten to sixty minutes, and is accompanied only by a slight fleeting decrease in the blood-pressure. On the injection of 0.25 to 0.5 gramme for each kilogramme, a considerable fall of the pressure and a great acceleration of the pulse rapidly follow. An intravenous injection of 3 grammes per kilogramme produces a further fall of pressure and a fleeting increase, with a subsequent sudden enormous decrease in the frequency of the pulse, the animal dying from cardiac paralysis. Experiments show that the quickening of the cardiac action is dependent upon the syrup acting on the peripheral ends of the vagi. In all cases intravenous introduction of the syrup rapidly produced a strong sedative effect, "the animal remaining strikingly quiet, and giving no response to tactile or even pathic irritation." Another group of experiments showed that the diuretic action of melon-syrup was dependent mainly upon its direct influence on the renal tissue.—*London Medical Record*, June 15, 1886.

The Prevention of Insanity.—In a paper recently read before the Connecticut Medical Society, Dr. Gustavus Eliot presents the following conclusions, which, although they have no claim to the merit of novelty, are none the less important:

In order to prevent the occurrence of insanity it is necessary

I. To avoid the transmission of a hereditary tendency thereto, by discouraging marriage between persons of like tendencies in this direction.

II. In persons with a hereditary or acquired tendency in this direction, to counteract the tendency as far as possible.

1. By insuring regularly an adequate amount of sleep, and a sufficient quantity and variety of nutritious food.

2. By securing recreation and relaxation.

3. By maintaining the action of the secretory and excretory organs.

4. By avoiding entirely the use of alcohol and other cerebral stimulants.

5. By cultivating habits of self-control.

6. By encouraging objectivity rather than subjectivity of thought, breadth, and not narrowness of mental activity.

7. By avoiding anxiety and excessive mental exertion.

8. By taking disappointments philosophically, forgetting them quickly, and not brooding over the unpleasant occurrences of the past, but anticipating with cheerfulness the events of the future.

Further Investigations on the Bacillus of Typhoid Fever.—Neuhauss has continued his study of the contents of the roseola spots of typhoid and, as before, finds in the blood therefrom obtained a characteristic bacillus. Only the blood from these spots contains the bacilli, a fact which inclines him to the opinion that the cutaneous lesions are due to "bacterial emboli." In nine out of fifteen cases he has succeeded in making cultures of the typhus bacillus from blood thus obtained.

Neuhauss claims also to have found the bacilli in the four months' fœtus of a woman who aborted soon after a relapse of typhoid fever. Inasmuch, however, as a conclusive proof of the passage of microörganisms from the maternal to the fœtal circulation is not yet at hand, the statement demands further investigation.—*Centralbl. f. klin. Med.*, July 31, 1886.

Extirpation of the Spleen.—Prof. Ceci, of Genoa, successfully removed the spleen in a girl, aged seventeen (*Gazz. degli Ospitali*, May 23). The patient, who was imperfectly developed and ill-nourished, had had an abdominal tumor from birth. A large floating spleen was diagnosticated. It interfered with the patient's walking, and at times gave rise to severe attacks of pain extending from the left hypochondrium to the præcordial region, radiating into the left arm, and followed by dyspnœa and unconsciousness. The removal of the organ was therefore decided upon. The operation was performed on March 20. The strictest antiseptic precautions were used, and the surrounding atmosphere was at a temperature of 30° C. (86° F.). Anæsthesia was commenced with bichloride of methylene; but upon opening the abdomen grave symptoms of suffocation appeared, which necessitated the suspension of the operation for nearly thirty minutes. Chloroform was then employed. The incision was twenty-three centimetres (nine inches) long; and extended through the linea alba, an equal distance above and below the umbilicus. The pedicle was secured with a triple ligature of catgut and carbolized silk, and was left at the bottom of the wound. The peritoneum was sutured separately. The abdominal walls were fastened by three metallic points, after Billroth's method. The extirpated organ with its contained blood weighed about 2400 grammes (a little short of five pounds). The whole operation, including the above-mentioned interruption, occupied an hour and a quarter. Furious delirium came on the following morning with the nervous symptoms, resembling *angina pectoris*, from which the patient had been in the habit of suffering. For two days, the respirations were from 70 to 80 a minute, and the pulse could not be counted. Under treatment by oxygen and nutrient clysters this alarming state passed off. On the fourth day, fever arose. On the eighth day, the first dressing was removed and the wound was found actively suppurating. The suppuration, according to the report, yielded to vigorous antiseptic treatment. In the following days, however, occurred two erysipelatous infections, coincidently with the reception of two erysipelatous patients in neighboring surgical wards. At the time of the report (April 22, 1886) the patient was in excellent condition. The abdominal incision had nearly healed, showing only a superficial wound remaining. This is stated to be the thirty-ninth time the operation has been performed. The mortality has been 78 per cent.—*London Medical Record*, July 15, 1886.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

SATURDAY, SEPTEMBER 11, 1886.

EXCISION OF VARICOSE VEINS.

IN speaking of the method of Antyllus for the treatment of aneurism (THE MEDICAL NEWS for May 1 and May 29, 1886), we have already expressed the opinion that modern improvements in the mode of performing surgical operations and in their after-treatment make it possible to form more favorable opinions of certain operations than were once justifiable. This is the case with the method of excision of varicose veins. There was a time when it could not be questioned that any method which attacked them through an open wound made the patient liable to serious accidents, and even to death. This fact accounts for the preference evinced by some of the most experienced and skilful surgeons for the employment of caustics, and the efforts made to devise a satisfactory method of subcutaneous ligature. But, at the present time, when the most intolerant parts are attacked with impunity every day, it is not an act of temerity to cut down upon, and remove portions of, veins which are enlarged and tortuous, so as to relieve the often distressing symptoms to which they give rise. Indeed, something more than has been effected in this direction might have been hoped for from the elaborate papers of DR. SAMUEL W. GROSS on wounds of the veins, published in the *American Journal of the Medical Sciences* in 1867, in which he made it clear that the veins are not so intolerant of operative interference as has been supposed.

This fact is better understood now than it was then, and so it is not surprising to find a revival of interest in the method of treating varicose veins by excision, which is as old as the time of Celsus. Its latest advocate is DR. KENDAL FRANKS, who publishes an interesting paper on this subject in the *Dublin Journal of Medical Science* for May, 1886. In this paper Dr. Franks, after discussing the pathogenesis of varicose veins—speaking of those of the legs alone—describes his method of excision, and the cases to which he believes it to be suited. In slight cases, in old and debilitated subjects, and in cases in which the condition is due to irremediable extrinsic causes, he thinks palliative measures are to be preferred. But where the cause is intrinsic, or is extrinsic and remediable, and where the patient is a young, or healthy adult, he would operate. In fact, he has operated in more than twenty cases, and in none has he seen phlebitis, erysipelas, or pyæmia, formerly the great terrors of the operation. Of course, he uses aseptic precautions. He washes the leg with corrosive sublimate solution, or oil of eucalyptus; places a ligature around the limb above the site of the proposed incisions, so as to distend the veins; makes a clean cut over the vein; divides the subcutaneous tissue on a director; passes a strong catgut ligature around the vein at its lower part; seizes it immediately above the ligature in a pair of forceps, cuts through it below them, and draws it out, ligating and dividing any radicles met with. Finally, he places a ligature around the highest point of the strip which has been dissected out, and cuts it off just below this ligature. He then irrigates the wound with corrosive sublimate solution, dusts it with powdered iodoform, and closes it up. Formerly he used to insert a drainage tube; but he no longer does so. If necessary, he removes several sections of the vein or veins in this way, and he also operates at once on both legs, if they both need it. After the operation he bandages the leg, or legs, from the toes to above the knees. As a rule, he leaves the dressings undisturbed for eight or ten days, and generally finds the wounds healed by first intention when he examines them. In a few cases he has had some suppuration, but it did no more harm than to delay the healing for a little while. He does not state that he puts his patients to bed after the operation, but it is to be assumed that this is done.

The confidence of Dr. Franks in this method is not surprising, in view of the good results he has obtained by it, and especially in view of the fact that he believes he secures a radical and permanent cure. His own conclusion is that antiseptic excision, in suitable cases, is a means of treating varicose veins which offers the hope of far better and more permanent results than any other method hitherto devised, and that with ordinary care it is far safer. This conclusion certainly seems warranted by the argument of Franks, and would justify imitation of his example.

It is interesting to note that this experience furnishes another illustration of the fact that the practice of modern surgery returns, from time to time, to the simple and direct methods of the ancients; and with its gains in the direction of more accurate *technique* and more perfect conditions of asepsis, secures better results by once abandoned methods than have been obtained by the methods to which men were driven by the dangers of the pre-antiseptic period. In operations upon the skull, in operations on the abdomen, in operations upon the bladder, the same thing is being seen; and surgeons are continually reverting to the plainer and more direct methods of the earliest surgeons. Simplicity and directness seem to be coming into fashion. Even the very features of the antiseptic method of wound treatment, which is not yet old, are becoming simplified; so that it may be hoped that before long the principles of surgery will have attained a degree of perfection which was not possible in the earlier, ruder days, nor yet in the days of extreme reaction, in which too much stress was laid upon unimportant details.

THOMSEN'S DISEASE.

In 1876, Thomsen, a Schleswig physician, described a remarkable affection of the muscles to which he was himself subject, and which had existed in many members of his family through, at least, four generations. The disease has, since then, become well recognized, and is usually known by the name of the original describer, or by the term myotonia congenita, suggested by Strümpell. In a recently issued monograph, *Die Thomsen'sche Krankheit*, Leipzig, 1886, Erb has analyzed all the recorded cases, and presented an elaborate study of the affection, based upon three original observations.

The disease involves the voluntary muscles, and, as a rule, appears very early in life; indeed, in a majority of cases, it is probably congenital, and often affects several members of the same family. It is characterized by a remarkable stiffness and tension of the muscles on attempting to perform any voluntary movement. This is particularly noticeable after the subject has been at rest for some time. Occasionally the entire body becomes stiff, and the patient may be unable, for a few moments, to move a limb. Usually the tension and stiffness pass off with continued motion, and the action of the muscles becomes as free as in a normal individual. Rapidity of muscular action is impossible, as with each energetic willed movement the muscles involved pass into a tonic, long-continued, painless contraction which is only gradually relieved. In all other respects the subject of this disease is healthy, and presents neither psychical nor somatic anomalies. The muscular system is unusually well developed, but the strength is scarcely proportionate to the size and appearance of the muscles.

Hereditary influences play an important part in the etiology, and the disease resembles several other myopathic affections in appearing early in life and attacking several members of the same family. It is essentially a chronic malady, and may persist, with variations in intensity, during the entire life.

Of the recorded cases Erb has selected twenty as typical instances, and has excluded twelve or fifteen as doubtful. A careful study of his three cases led to the discovery of certain symptoms of diagnostic importance, hitherto overlooked, and also to certain facts which throw light on the pathology of the disease. The mechanical excitability of the motor nerves is not heightened, and the faradic and galvanic reactions are essentially normal; but the muscles, on the other hand, show a greatly increased excitability and qualitative changes with galvanism. AnS acts as strongly as KaS, often, indeed, more strongly, and the contractions are slow, tonic, and long continued. The strong faradic current induces in many muscles undulatory contractions. Great stress is laid upon this marked difference in the nerve and muscle reactions as the important diagnostic sign of the disease.

In the portions of the muscle excised during life remarkable changes were found, consisting in enormous hypertrophy of all the fibres, increase in the nuclei, indistinctness and vacuolation of the substance, with thickening of the interstitial connective tissue. An opportunity of examining the nervous system has not yet arisen, but Erb holds that the evidence points strongly to a pure myopathic affection, and he would directly connect the disturbance in function with the histological changes discovered in the muscles, the precise nature and mode of origin of which still remain in doubt.

The affections with which Thomsen's disease is most likely to be confounded, are tetany and pseudo-hypertrophic muscular paralysis. The tonic spasm in the muscles occurring at intervals resembles tetany, but the contractions are never so strong, are not painful, and do not occur spontaneously, but always on attempting a voluntary act. The hereditary and chronic character of Thomsen's disease also afford valuable diagnostic features. The nerve and muscle reactions are entirely different, as the excitability of the nerves in tetany is heightened, while that of the muscles is normal—the reverse of what occurs in Thomsen's disease. In several instances the affection has been confused with pseudo-hypertrophic paralysis, with which, however, it has only a superficial resemblance in the hereditary origin, the early onset, and the increase in volume of the muscles.

The disease is probably incurable and does not appear to lessen the duration of life. Erb recommends massage and general faradization as suitable agents, the former for direct action on the muscles, and the latter as a tonic to the trophic centres.

A PROPOSED MODIFICATION OF PORRO'S OPERATION.

Dr. John Bartlett, of Chicago, proposes to modify the operation of Porro by first opening the uterus with a thermo-cautery instead of the knife, and, after the removal of the fœtus and secundines, to invert the organ, clamp the cervix in the vagina, and then amputate as in the Porro method, leaving the stump in the vagina. The proposition is ably presented in a paper which was read before the Chicago Gynecological Society on June 26th. This plan was proposed in Europe in the early days of the Porro method, to avoid the dragging of the pedicle upon the abdomen, and the risk of dropping in the stump for the same purpose, as devised by Gustav Veit, of Bonn; but no one in the six years that have passed has thought sufficiently well of it to give it a trial. It is, therefore, not new, and at the present time the Porro method is being in a measure superseded by a less dangerous one in an improvement of the old Cæsarean operation devised by Dr. Sänger, of Leipzig. There is no hope from theoretical reasoning, that the Bartlett plan would ever be able to save 80 per cent. of the women, and nearly 100 per cent. of the children, as has been done in Continental Europe, under the Sänger method, and it is, therefore, only to be regarded for its ingenuity.

The Porro operation of to-day has not the status that it had three years ago, or even one year ago, for the wonderful results under the old Cæsarean section with the Sänger improvement have excited the attention of some of the most famous of the followers of Porro, who are now making trial of it because of its lesser fatality. When the operators in two maternity hospitals have saved 16 out of 17 women, and all of the children, by it, there must be more in it than an accidental train of good fortune. The Porro method, even under Chiara, of Milan, was made to appear more dangerous by comparison, and Chiara himself reports as an entire success a trial of the new plan made just three days after Dr. Bartlett read his paper.

When we consider that in the year from July, 1885, to July, 1886, there were 20 Sänger operations in Europe, with a loss of only 2 women and possibly child, we can comprehend the futility just now of recommending any other scheme of delivery in cases of pelvic obstruction. Mr. Lawson Tait, having lost three women by the Cæsarean section, and saved one by the Porro method, may prefer the latter, and rate the mortality of the former at over 99 per cent., but he cannot establish his estimate in view of these incontrovertible facts. Until a wiser man devises a safer method, we shall recommend that of Sänger as simplified by Leopold, for it has saved 90 per cent. of the European cases in the past year. In 1880, there were 27 Porro operations (true) in Europe, resulting in the saving of 10 women and 21 children. In 1883, there were 12 recoveries and 10 deaths, which is the best year in Dr. Godson's table. In no year were 18 women saved from any number of operations. The 31 Sänger Cæsarean operations of Europe have been the work of 13 operators in Germany, Austria, France, and Italy.

REVIEWS.

Monthly Nursing. By A. Worcester, A.M., M.D., Fellow of the Massachusetts Medical Society. 8vo. pp. 250. Boston: D. W. Mason, 1886.

The author of this little volume has been in the habit of lecturing to nurses in the Boston Lying-in Hospital, and more recently in the Waltham Training School, and this may be said to be his text-book designed especially for their instruction. It aims rather high for the class of women who usually offer themselves to nurse parturient cases, but not too much so for those who ought to be trained for this important branch of nursing. The better educated and more refined women who enter training schools generally prefer to nurse ovariotomies and other surgical cases, neurasthenias and other nerve maladies, etc. Dr. Worcester designs by his book to teach what is to be done in cases of emergency, and to give an obstetrical training, so that the nurse may be prepared to act in cases where the physician is not on hand at the delivery. Although he adds a glossary to the end of the book, we believe it would have been better either to have avoided technical terms, or to have explained them as in *Blundell's Midwifery*, at the bottom of each page where they occur. The general aim of the book is to teach nursing only, and to make the nurse observant, careful, and competent in her position. There is no reason why women with a fair degree of education should not be trained to nurse in cases of labor, and be well compensated because of their superior knowledge. There are many female medical students and graduates who might do better in this capacity than in an overcrowded profession, but for the fact that so few of them have the requisite physical health and strength, but there are others in various trades and occupations in which they make a bare living, who have these requisites and might better their resources in nursing. The volume closes with a section upon diet. We cordially recommend the work, and believe that it will be useful not only in the hands of nurses, but in those of many physicians who need to know how to direct them.

SOCIETY PROCEEDINGS.

THE AMERICAN DERMATOLOGICAL ASSOCIATION.

Tenth Annual Session, held at Greenwich, Conn., August 25, 26, and 27, 1886.

THURSDAY, AUGUST 26.—SECOND DAY.

MORNING SESSION.

DR. G. H. TILDEN, of Boston, read a paper on

TROPHONEUROSIS OF THE SKIN CAUSED BY INJURY TO THE MEDIAN NERVE.

E. F., fifty-five years of age, was wounded in the wrist by a circular saw, in November, four months before coming under observation. The wound was parallel with the long axis of the limb. It was sewed up and healed in about ten days. Three or four days after the infliction of the injury, there were loss of the tactile sense and a feeling of numbness in the last two phalanges of the fore- and middle-fingers. This has continued and steadily increased. There was at first a slight feeling of numbness in the thumb, but this gradually diminished until it disappeared. Three weeks after the accident bullæ appeared upon the terminal phalanx of the middle finger. Similar lesions have developed from time to time upon the last two phalanges of the fore- and middle-fingers. The bullæ appear every two or three weeks and are unaccompanied by any subjective sensation. These leave superficial excoriations which heal in the course of ten days. The skin over the affected phalanges is of a white color and of a glossy texture. The growth of the nails is unaffected. There was entire loss of sensation in the skin covering the affected phalanges. The right hand is capable of exerting only one-half the power of the left. The first and second interossei muscles exhibited the reactions of degeneration. Six weeks' treatment with the faradic current caused decided improvement in all the symptoms. During this period only one bulla formed. He then stopped treatment and returned to work. Three weeks later all the former symptoms suddenly returned. It was proposed to the patient that an incision be made over the seat of injury with the view of determining the exact condition and if possible remedying it. The patient has not since been seen.

Whether the trophic nerves exist as individual and special nerve fibres or whether the motor and sensory nerve fibres are the ones by which the nutrition of the tissues is governed, is unknown. The latter view was considered by the author as the most rational. Injury or disease of the motor or sensory nerves as well as disease of the ganglia and central nervous system, may disturb not only motor power and sensation, but also the nutrition of the tissues. That it does so is by no means the case, but why trophic changes should take place in one instance and not in another is not clear. A number of cases have been reported showing that such changes are more apt to follow partial injury of a nerve than complete section. The changes commonly seen in these cases are the so-called glossy skin and vesicular and bullous eruptions followed by superficial excoriations. The treatment of these cases consists in the use of electricity and the application of blisters over the seat of injury. A last resource is to cut down upon the affected nerve and endeavor to relieve any constriction or pressure which may be found. If no such condition is detected, resection of a portion of the nerve might be advisable, since complete section is not apt to be followed by spontaneous trophic changes, and since it has been found by some observers that resection of a portion of the affected nerve is sometimes followed by arrest of the trophic changes.

DR. JAMES C. WHITE, of Boston, then presented a paper on

NATIVE PLANTS INJURIOUS TO THE SKIN.

He pointed out that the number of plants growing native and cultivated in the United States, which are capable of exciting some degree of dermatitis by contact, is much larger than is generally supposed; and that cases of such inflammation of the skin not infrequently occur without being understood, because the patient has not been exposed to the two or three plants which alone are considered to be poisonous. He enumerated over fifty species which have irritating properties when brought in contact with the skin. With reference to rhus poisoning he said that the rhus toxicodendron is comparatively innocuous, while the rhus venenata is the most poisonous species of this plant. The treatment is the ordinary treatment of dermatitis. There is no specific for this form of dermatitis.

DR. H. G. PIFFARD, of New York, read

SOME NOTES ON DRUGS,

in which he referred briefly to several recently introduced preparations.

DR. F. B. GREENOUGH, of Boston, presented

A FEW ADDITIONAL NOTES ON PSORIASIS.

The paper was a continuation of the tabulation of cases of psoriasis seen during the past year. The facts previously noted with reference to age, sex, the time of the first appearance of the disease, and the number of cases, had been confirmed. In addition to these statistics, the author, owing to the fact that a statement he had made at the last meeting in reference to the general health of the patients, had been doubted, had attempted to obtain further testimony upon this point. He found that, as a rule, patients with psoriasis were above par in general health and strength. He had records of twenty-nine cases of psoriasis out of 1220 cases of skin diseases, giving a ratio of cases of psoriasis of two and one-third per cent. The youngest case was nine years of age, while the eldest was fifty-seven years. The reader thought that the interesting deductions to be drawn from his cases were the facts, that while nine cases showed symptoms of psoriasis under ten years of age, one was first attacked at the age of fifty-seven years; that out of twelve cases in which evidence could be obtained, four gave a decided history of the existence of disease in some member of the family, and that these cases showed such a high standard of general health. He considered this latter fact as a strong argument against the possible connection between psoriasis and syphilis. He had never seen psoriasis of the hands unassociated with evidences of the disease in other parts of the body.

DR. A. R. ROBINSON, of New York, described a case of

CHONDROMA OF THE UPPER LIP.

The tumor occupied the right side of the upper lip of

a man thirty-six years of age. It had been growing for two years and was one inch in length by three-fourths of an inch in diameter. The mucous and cutaneous structures were freely movable over the tumor, which was sharply limited, somewhat encapsuled, and nourished by a small artery entering at the base. Microscopical examination showed the tumor to consist of embryonic, gland and connective tissue. The gland tissue was formed of hypertrophied mucous glands and new gland tissue. The amount of new gland tissue could not be correctly estimated, because much that resembled gland tissue, represented an early stage in the process of cartilage tissue formation. The connective tissue was myxomatous, fibrous, and cartilaginous. The myxomatous was present principally at the periphery and did not represent œdematous fibrous tissue. Fibrous connective tissue was present chiefly between the islands of cartilages, the bundles were small and the fibrils very fine and often rather indistinct in outline. There were several islands of cartilage the largest being in the central part of the tumor. All varieties of normal cartilage were present, viz., hyaline, fibrous, and reticular, and also the variety met with in the heads of cephalopods, namely cartilage with ramifying or branched cells, *chondromes à cellules ramifiés*. The cells showed great diversity of form and size. The body of the branched cells presented a great variety of form. Some were surrounded with a capsule, but in the majority of cases this was absent, or only faintly indicated. In some places the islands of cartilage had joined each other, but usually they were separated by the other constituent tissues. The affection is considered to be very rare. It has been described by Paget under the name of labial glandular tumors.

DR. P. A. MORROW, of New York, reported a case of

KERATOSIS FOLLICULARIS, ASSOCIATED WITH FISSURING OF THE TONGUE AND LEUKOPLAKIA BUCCALIS.

The patient, C. O., a sailor, aged twenty-one years, came under observation in December, 1885. Five years previously, soon after beginning his seafaring life, he noticed a number of blackish points upon the back of the hands, some of which he squeezed out. Soon afterward these appeared upon other parts of the body. They improved when he was on land, but were aggravated when he was at sea. The entire surface of the body, with the exception of the face, palms, and soles, was found to be the seat of the follicular disorder. The ducts of the sebaceous glands were occupied by comedo-like bodies, projecting sometimes one-fourth to one-half an inch above the surface. From many of the follicles small white hairs protruded. The comedos, when pressed out, were hard and dry. The hard portion of the comedo was continuous with an adhesive substance dipping deeply into the follicle. There was no evidence of irritative or suppurative action. They were not accompanied with itching.

The tongue was large and rough to the touch; the surface was deeply fissured, the fissures extending to the submucous tissue. The buccal mucous membrane presented a bluish-white appearance, thickened and raised in places, forming distinct plaques, which were superficially fissured. The patient stated that the tongue had been white and a little sore ever since he could remember. The absence of irritation, or marked sensitiveness of the fissured organ was quite noticeable. Examination seemed to exclude the possibility of a syphilitic origin. The speaker referred to other cases which had been reported. He objected to the term ichthyosis, since that suggests a disease of a different nature. He selected the term keratosis follicularis as more correctly expressing the pathological condition present, as well as indicating the anatomical seat of the disorder. Drawings representing the microscopical appearances of the lesions were presented.

While in the hospital the patient improved decidedly under the use of local applications of linseed oil. But within a short time of the discontinuance of the treatment, the condition became as marked as before treatment was employed.

EVENING SESSION.

DR. J. E. GRAHAM, of Toronto, presented

A CLINICAL STUDY OF SCLERODERMA.

He first related the histories of two cases of this rare disease, one of which occurred in the practice of Dr. Smith, of Seaport, Ont., and the other was referred to him by Dr. Jenner, of Pictou. The first patient, Mrs. R., forty-seven years of age, had previously suffered from rheumatism. The hardening of the skin began in March, 1882, and was first noticed over the back of the neck. It gradually spread, so that in about ten weeks the integument over the greater part of the body was affected. The movements of the limbs, as well as those of respiration, were impeded. The internal treatment adopted was liquor ferri iodidi and liquor arsenitis. A faradic bath over the surface of the skin was used. In six weeks the skin began to grow softer, and in ten months the patient was quite well. There has been no return of the difficulty.

The second patient, Mr. H., aged thirty-seven, came under observation in May, 1886. There was a history of hereditary rheumatism. The disease had commenced some months previously. The first symptoms were stiffness of the limbs, with œdema of the lower extremities; then hardening of the skin over the hips was noticed. This gradually spread, and was accompanied with pigmentation. The treatment consisted in the administration of potassium iodide at first, and latterly of salicylate of sodium. There has been some improvement under this treatment.

In his remarks in connection with the disease, the speaker referred to the following points: 1. That the disease is found principally in temperate climates, and occurs in seasons when there are sudden changes in the weather; 2. That it is more closely related to rheumatism than has been supposed; 3. That, although morphœa has in all probability a similar pathological origin to scleroderma, yet the clinical distinctions are so marked that at present it is expedient to treat it under a different name.

DR. L. N. DENSLOW, of St. Paul, in one case of scleroderma in which were two large plaques on each pectoral region, had seen benefit follow the daily use of the constant current, continued for six months.

DR. DENSLOW then reported a case of

CARCINOMA CUTIS.

The patient, aged forty-nine, had had a severe right-sided pleurisy, and presented the physical signs of ab-

sence of the right lung. The skin of the right chest from the second to the seventh rib, and from the posterior border of the axilla to the median line, was covered with a nodular new growth, which presented no ulceration. Around the nipple the nodular mass for an area of six square inches reached a thickness of an inch. The older portions of the growth were covered with thickened epidermis with thick brown scales. There was slight enlargement of the axillary glands. The whole mass was free from the fascia. It was not painful on pressure, but was the seat of occasional neuralgic pains. The duration of the growth was seven months. The patient died four months after coming under observation. The autopsy showed obliteration of the right lung. The left lung presented many small, solid nodules. In the mesentery there was a nodule an inch and a half long by one-half inch in diameter. The microscopic examination of these masses showed that in them all connective tissue preponderated. The growth on the skin occupied the papillæ and the deeper portion of the corium, and here, too, connective tissue greatly preponderated.

DR. I. E. ATKINSON, of Baltimore, referred to the extremely malignant nature of these growths. In a case of his own which presented appearances similar to that of Dr. Denslow's case, the disease ran its course in two or three months. These cases are so malignant that it would seem that no operative procedure is justifiable.

DR. R. W. TAYLOR, of New York, referred to two cases, both in men, which were, for a time, looked upon as cases of cancer of the nipple. They eventually turned out to be cases of hard chancre; in one the induration was so great that carcinoma was strongly suspected.

DR. I. E. ATKINSON, of Baltimore, read a paper on

SCARLET FEVER AND SCARLATINIFORM ERUPTIONS FOLLOWING INJURIES AND OPERATIONS.

He first referred to the cases on record. In many of these it was held that the affection had been a true scarlatina. In others the scarlatiniform rash was of a septic origin. Various drugs which are frequently prescribed in traumatic cases will produce such eruptions, special reference being made to the cinchona alkaloids. The following conclusions were presented:

1. Unprotected persons who have suffered injury or undergone operation are much more liable to scarlet fever than are healthy individuals. This probably holds good with reference to other infectious diseases.

2. When an epidemic tendency to these symptoms prevails after injuries and operations, it may be concluded that true scarlet fever is present.

3. Septicæmia is occasionally accompanied with a scarlatiniform eruption.

4. Medicinal eruptions, especially from cinchona alkaloids, may follow accidents and injuries.

DR. P. A. MORROW, of New York, said that a rash often follows the use of antipyrine, which frequently simulates scarlatina, although it is usually of a more measley character. Again, carbolic acid and iodoform dressings will often produce eruptions presenting the objective appearances of scarlet fever. There is another eruption known as the "doctor's rash," which appears upon the persons of sensitive individuals stripped for examination.

DR. L. N. DENSLOW related the case of a young woman who stated that a scarlatinal eruption always appeared upon her body on exposure to sunlight. In order to test the matter, she was directed to come to the hospital closely veiled and gloved. She was then placed in a dark room and one glove removed. A ray of sunlight was then allowed to fall upon the hand and at once a strip of erythema appeared. The same occurred on the face when it was exposed.

DR. I. E. ATKINSON, in closing the discussion, said that while he had seen the rashes mentioned by Dr. Morrow, he did not consider them in his paper, because he was specially interested in those scarlatiniform eruptions following traumatism, and he referred to medicinal eruptions only incidentally.

FRIDAY, AUGUST 27—THIRD DAY.

MORNING SESSION.

DR. S. SHERWELL, of Brooklyn, made some

REMARKS ON AND QUERIES AS TO THE RELATIVE FREQUENCY OF MOLES AND THEIR PATHOLOGICAL CHANGES ON THE HEAD AND FACE.

This class of affections receives very little consideration in works on dermatology, but the author's experience had led him to pay increased attention to these formations. In looking up the statistics of one of the institutions with which he is connected, he found that in a period of eighteen months, he had seen forty-seven cases suffering with neoplastic and hypertrophic growths. In thirty-six of the cases, the growths occupied the face and head. In only eleven cases were the growths found on the body and limbs. Seventeen of the cases, in which the growths were on the face, were classed as epithelioma. It might be urged that the exposure of the unclothed portions of the body would lead to the formation of neoplasms and the occurrence of destructive activity in them. If that were so, why should not telangiectatic deformities, nævi, etc., undergo degeneration? The speaker had never seen malignant action or what simulated it in such growths. Mechanical irritation of the parts might be considered one reason for the frequency of these growths and their malignant tissue alterations. But other parts of the body would seem more exposed to irritation than is the face. Moles, and similar growths, are common on other parts of the body as well as on the face, yet in other situations they seem less likely to undergo destructive pathological changes. The field electively most inimical to the presence of these growths, and destructive activity in them when already present, is a quadrangle just taking in the lower lip, the corners of the mouth, extending back to the ears of both sides and extending upward to about an inch above the supraorbital ridge. Of the space thus included, the vicinity of the eyelids and bridge of the nose, was, in the author's experience, the most usual seat of these growths.

The most rational explanation for the frequency of these growths in the situation described, is the nature and abundance of the circulatory nutrition, which must favor hyperplasia. If, however, we accept the above hypothesis, why should these errors of the capillary system, such as nævi, not oftener degenerate? He had frequently operated on these latter deformities, often causing much irritation, but had never seen more than

a slight keloid change result. The speaker then referred to the special danger of malignant degeneration which attends the presence of moles in persons of advanced life.

In regard to treatment, he stated that he had operated on these growths in many ways, and had come to the conclusion that when malignant action is either present or suspected, the combination of Volkmann's curette, followed by the potential cautery, is the most efficient and easiest method of treatment. Of all escharotics, he preferred the liquor hydrargyri nitratis.

DR. I. E. ATKINSON thought that the probable explanation of the frequency of the presence of moles, etc., upon the face as compared with other portions of the body, is that when in this situation patients seek relief, while when covered with the clothing attention is not attracted to them. We should expect that sebaceous new growths would be more commonly seen upon the face, because there we have the greatest activity of the sebaceous apparatus.

DR. JAMES C. WHITE, of Boston, considered that these new formations referred to are not more frequent on the face than on other portions of the body. That they undergo degeneration and form epitheliomatous new formation on the face more frequently than on other parts of the body, he thought, could not be doubted. He had never seen angiomatous formations undergo the so-called malignant change, but they do undergo degenerative processes tending to a spontaneous cure. Formerly he had used the liquor hydrargyri nitratis to a large extent as an escharotic, but within recent years he had substituted the concentrated nitric acid, and the effects obtained seemed to be about the same.

DR. L. N. DENSLOW said that for the past year he had used a solution of one drachm of bichloride of mercury in one ounce of traumatacine. Its application is not painful at first and does not excite inflammation for some time. It is particularly useful in the case of children.

DR. R. W. TAYLOR remarked that the author was to be congratulated upon the clear manner in which he had called attention to the danger of these various growths upon the face in a person over forty-five years of age. Such growths are very prone to assume malignant action. In the same connection, it may be remarked that any inflammatory mass about the prepuce, particularly if the result of anterior lesions, should, in old persons, always be ablated.

The Secretary read the

NOTES OF A CASE OF EXFOLIATIVE DERMATITIS (PITYRIASIS RUBRA ?), WITH BULLOUS LESIONS,

by DR. W. A. HARDAWAY, of St. Louis, who was unavoidably absent.

The patient, forty-five years of age, stout and somewhat nervous, was seen February 21, 1886. He had always been healthy. The present disease came on Feb. 1st, after a night of fatigue and exposure when heated. The following day a red patch appeared on the pit of the stomach. Others developed, soon running together, leaving no healthy skin between. There was very little scaling at first and no moisture. There was some degree of pruritus. When seen by the author the chest, arms, back, and thighs presented the usual appearances of pityriasis rubra. There was no moisture, crusts, or appreciable infiltration. The skin was shining and of a violaceous hue. In the morning a handful of scales could be gathered from the sheet, but they were not as large as usual and were inclined to be furfuraceous. The face was not involved. Three or four days after the first visit, there appeared upon the thighs, abdomen, and buttocks a number of tense bullæ. Their appearance was preceded by a distinct chill and followed by a moderate elevation of temperature. The blisters did not run into each other. The bullæ appeared in successive crops of not more than a dozen, each crop being preceded by a chill. Quinine was freely administered and at the end of a week the bullæ ceased to appear. Dr. Hardaway was obliged to discontinue his visits at this period of the case, but the patient gradually improved.

The writer thought that this and other cases which he had seen showed that diseases usually supposed to run a dry course, may under certain circumstances be complicated with lesions containing fluid.

DR. G. H. TILDEN, of Boston, reported

A CASE OF PROBABLE TUBERCULOSIS OF THE SKIN.

A healthy-looking boy of two years of age was first seen in July, 1885. There were six or eight cutaneous lesions scattered over various parts of the body. These were about the size of a split pea, slightly elevated above the level of the skin of a bright red color, which disappeared entirely on pressure. These nodules were hard to the touch with borders of sensible infiltration. They had appeared within the previous five months and had been very slow in growth. During the previous three months there had been failure in appetite and strength, and the child showed an indisposition to walk. He was under observation for three months, during which time one or two fresh nodules appeared. In nearly all the older ones, there ensued softening with formation of pus, which discharged and was followed by cicatrization. About two weeks after the first visit a fluctuating swelling the size of a hen's egg made its appearance on the inner side of the left thigh over the knee-joint, but not communicating with it; this was opened and pus discharged. It healed within a week. The general health became visibly affected. In November there appeared in the left buttock a swelling which gave an obscure sense of fluctuation. In the proximal phalanx of one finger there appeared a pyriform enlargement resembling that seen in dactylitis syphilitica. The child was again seen in February. The swelling in the buttock had increased in size and there was more fluctuation in it. There was at this time, sufficient outward curvature of the lumbar vertebræ to justify a diagnosis of Pott's disease. In his remarks with reference to the case, the speaker said that in the outset the diagnosis of the nature of the cutaneous lesion had been impossible, but from the subsequent course of the disease he thought the most probable diagnosis to be tuberculosis of an unusual form.

DR. L. N. DENSLOW made a supplementary report with reference to

THE TREATMENT OF ACNE BY THE USE OF SOUNDS.

At the last meeting he had reported five cases in which this plan of treatment had been of value. Four of these cases were adults, and all had remained well.

The fifth case was that of a boy about fourteen years of age, and in this case relapse had occurred.

Dr. S. Sherwell, of Brooklyn, stated that he had treated three cases of acne with the use of sounds, and believed that it was useful. He employed this method as an adjunct to other treatment.

A communication with reference to the organization of

A CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

was received and the following committee of conference, to report at the next meeting of the Association, was appointed: Drs. H. G. Piffard, of New York; F. B. Greenough, of Boston; R. B. Morison, of Baltimore; G. H. Tilden, of Boston; and Le Grand N. Denslow, of St. Paul.

The following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. H. G. Piffard, of New York.

Vice-Presidents.—Drs. F. B. Greenough, of Boston, R. B. Morison, of Baltimore.

Secretary.—Dr. G. H. Tilden, of Boston.

Treasurer.—Dr. Le Grand N. Denslow, of St. Paul.

The Association then adjourned, to meet at the call of the Council.

CANADIAN MEDICAL ASSOCIATION.

Eighteenth Annual Meeting, held at Quebec, August 18 and 19, 1886.

Medical Section.

Wednesday, August 18.—First Day.

Dr. Canniff, of Toronto, in the Chair.

Dr. Daniel Clarke, of Toronto, read an able paper upon

THE MEDICAL JURISPRUDENCE OF CRIME AND RESPONSIBILITY.

The following were the conclusions arrived at:

1st, the natural history of crime shows that brains of chronic criminals deviate from the normal type and approach those of the lower creation.

2d, that many such are as impotent to restrain themselves from crime as the insane.

3d, that immoral sense may be hidden from expediency by the cunning seen even in the brutes, until evoked by circumstances.

4th, no man can shake himself free from the physical surroundings in which he is encased.

5th, crime is an ethical subject of study outside of its penal relations.

6th, insanity and responsibility may coexist.

7th, some insane can make competent wills, because rational.

8th, the monomaniac may be responsible should he do acts not in the line of his delusion, which are not influenced thereby.

9th, many insane are influenced in their conduct by hopes of reward or fear of punishment in the same way as the sane; the rudiments of free will remain.

10th, many insane have correct ideas in respect to right and wrong, both in the abstract and concrete.

11th, many insane have power to withstand being influenced even by their delusions.

Dr. Sherman, of Ogdensburg, spoke very highly of Dr. Clarke's paper. He himself, it so happens, is often called into court in cases of crime, or to give evidence as to the validity of a will when the sanity of the testator is under dispute. He observes that the views expressed by Dr. Clarke upon these difficult questions coincide most closely with those which his own observation has led him to adopt.

Dr. Howard thought the general principles laid down by the reader of the paper could not be made the subject of discussion, for upon them the profession was entirely agreed. These principles and the reasoning upon which they were founded had been ably set forth by Dr. Clarke. It was a matter for regret that the members of the legal profession could not be induced to see the matter in the same light.

Dr. Sullivan was afraid that many alienists still thought differently from Dr. Clarke, but he was glad to find that this Association was so unanimous in holding such advanced views upon the important matter of criminal responsibility. Dr. Clarke has shown us the difficulties that lie in the way of making a diagnosis in cases of mental disease, but he has failed to point out the remedy. The difficulties are even greater than in organic disease, and younger men would seem to require that experts should lay down some definite rules for them. It is, indeed, a question whether the ordinary practitioner can, or should ever be requested to give an opinion as to the responsibility of a doubtful individual. He has himself once given an opinion as to the entire sanity of a man who, shortly after, proved to be quite out of his mind, and who, indeed, subsequently was the author of the tragedy which ended the life of the lamented Dr. Metcalfe, of Kingston. The alienists themselves still differed much, and much was required to bring them into line, when it was possible for a well-known superintendent to say, as had occurred recently, that in his asylum all the males were mad through masturbation, and all the females through criminal abortion.

Dr. Clarke remarked that no man should hastily decide an obscure case of insanity—*i. e.*, after one or two hasty interviews. Some forms of insanity can be easily diagnosticated by the general practitioner, such as dementia, melancholia with delusions, and acute mania; but in cases of delusional insanity, care should be taken not to draw conclusions too rapidly. If the truth is to be arrived at, the specialist giving evidence should not be upon any side, but should be placed in a strictly independent position. Advanced students now in Toronto have the advantage of practically studying mental disease in the asylum, where Dr. Clarke also gives practical lectures. Those instructed in this way can back up their opinions upon good pathological grounds. A definition of insanity can never be given. The old legal ground of a capacity to distinguish right from wrong has done untold harm. The only means he knows of by which an opinion can be arrived at is to institute a comparison between the man as he is and his former self, the idea of which is to be obtained by a careful investigation into his past history, habits, etc.

Dr. Howard would not be understood to say that the profession was entirely at one upon all the points alluded to by Dr. Clarke, but merely upon the great general principles, especially the abandonment of the crude test of knowledge of right and wrong. He thought

that in all cases an independent jury of experts should be named—men whose position should be free from any leaning to either side, and whose decision would be final.

DR. DUPUIS, of Kingston, read a paper upon

DIABETES MELLITUS.

DR. CAMPBELL said that his attention had been strongly directed to the importance of temporary glycosuria from a case recently coming under his observation. A gentleman who, during the season, partook largely of strawberries and cream, was examined for life insurance, and refused, owing to the presence of a large quantity of sugar in the urine. Dr. Clarke re-examined him a short time after his diet had been changed, and found it entirely free from sugar. Such cases were not so rare as might be thought.

DR. D. CLARKE alluded to the frequent appearance of sugar in the urine just before and during acute accessions of mania in the insane.

DR. GEORGE ROSS said that certain cases of glycosuria—persistent, not temporary, as in Dr. Campbell's cases—required to be carefully distinguished from those of diabetes proper. In the former we might have sugar present in the urine for a great length of time, perhaps for years, and yet the symptoms which characterize true diabetes mellitus not showing themselves at any time. It would seem, therefore, that there are two distinct pathological conditions, in both of which the persistent presence of sugar in the urine may be a factor—in the one case coexistent with average health, and in the other marked by a peculiar set of well-known symptoms. In his most recent work upon diabetes, Dr. Milner Fothergill devotes special chapters to these quite different disorders, remarking at the same time upon the confusion on the subject that still exists in the minds of many medical men. To emphasize this, he relates the history of a case somewhat as follows: A physician in India, examining the urine of a patient, found sugar, desiring to be certain of his tests, he applied the various solutions to the suspected urine and to his own, side by side. To his dismay, he found his own urine loaded with sugar. He had been up to that moment in the most perfect health. Uneasy, he returned to England, and was given a strict anti-diabetic diet. His health failed rapidly. After a time he abandoned all attempts at treatment, and resumed his customary diet and habits in every way, with the result of being soon restored to as complete health as he had enjoyed before. Examples of this kind should teach a lesson to be careful in prognosis, and in estimating the effect of any medicine or other treatment in any given case.

DR. HOLMES alluded to the liability of those who have been temporarily glycosuric from improper diet to become diabetic. Such persons should always be cautioned against continuing the use of such articles of food for fear of serious consequences ensuing. He thinks that those physicians are most successful in these cases who begin early with a strict dietary and persistently enforce it. Has had some experience of bromide of arsenic, and thinks highly of it.

DR. GRAHAM thinks we might throw these cases into three classes—viz., 1st, Temporary glycosuria; 2d, A mild form of diabetes; and 3d, A severe form. In some cases of the last series medicine and diet have no effect whatever, whilst the milder forms are distinctly amenable to treatment, and are thereby either much prolonged or positively cured. In odd instances a glycosuria will be produced by a certain article of diet, and by that alone; a case of this kind from peaches had come to his knowledge. He thinks bromide of arsenic decidedly beneficial. Whether a coincidence or not, he could not say, but since he had begun the use of this drug all his cases had done well. The last of these he would mention. Two brothers, aged fifteen and twenty-two, were severely injured in the same accident; both became diabetic, all the symptoms, when first seen, being very severe. The urine had now diminished from twelve or fourteen pints to five pints, whilst the specific gravity had fallen from 1.045 to 1.028, and even that high figure was mainly from an excess of urea, because there was only a trace of sugar present.

DR. JENNER, of Picton, Ont., read a paper on

ALIMENTATION IN SICKNESS.

He dwelt chiefly upon the growing importance of dietetics in the management of sick people, giving many examples of the results of neglecting this department in favor of medication with drugs. He thought that the Canadian schools, as elsewhere, did not give sufficient attention to systematic teaching of the principles of dietetics to their pupils.

DR. ECCLES had often experienced difficulties in the way of having food suitably prepared for invalids. When he thinks it of special importance, he examines the food himself and gives directions for its preparation. We all rely too much upon medicine and too little upon diet. He thinks it often important to insist more upon the systematic, and perhaps frequent, feeding of patients. Persons who are weak should be allowed to take a light supper. To objectors, he points out that animals mostly feed before sleeping. During digestion there is more blood in the abdominal organs and less in the brain, a condition favoring sleep.

DR. HOWARD expressed himself much gratified at the thoughtfulness which had produced such a paper. It often requires courage, especially on the part of a young practitioner, to tell people that what they require is sunlight, fresh air, and good food, and not medicine.

DR. TRENHOLME hoped that the time is coming when we shall hear much more about diet than in the past.

DR. CAMPBELL maintained that the subject of dietetics was by no means so neglected as the reader would have us believe. He thought that, at the present day, every lecturer upon practice of medicine felt it a duty to lay stress upon the management of diseased conditions by attention to the dietary.

DR. CANNIFF said that in the Toronto schools the subject of sanitary science received considerable attention, and the matter of dietetics also held a prominent part in this course.

DR. PLAYTOR, of Toronto, read a paper on

THE VALUE OF MORTUARY AND OTHER HEALTH STATISTICS.

He alluded to the work already done in this direction, especially in Ontario, but showed that nothing had yet been accomplished to procure complete statistics for the Dominion at large. He urged the importance of having the subject of collection of statistics constantly brought before the attention of the general government. He

requested the Association to name a committee for this purpose.

Dr. J. E. Graham, of Toronto, then read a paper upon

CONTAGIOUS PNEUMONIA.

Dr. Howard said that after thirty-seven years' practice, and after having given a good deal of attention to the subject, it was beyond his experience to have met with such a series of cases as seemed to imply the existence of contagion. He would therefore conclude that there must be, in reality, two forms of the disease—one contagious and the other non-contagious. He thinks that, when we get such groups of cases as those related by Dr. Graham, in which pneumonia would *seem* to have been contagious, we are dealing with a disorder in some way different from the ordinary form of lobar pneumonia. We cannot say this is ordinary pneumonia which has assumed a contagious character owing to the existence of certain peculiar circumstances. If we consider the inflammation of the lungs arising from putrid emanations, we must admit that it is probably not a simple pneumonia, and that much has yet to be learned concerning its exact nature, differing, as it does, in area and in its course from the latter. These clinical features must be remembered even in the face of the evidence adduced from culture experiments, etc. What do the oldest amongst us say? Have they ever seen a case of pneumonia where they considered it proper to secure isolation or disinfection? In cases suggestive of contagion, the greatest care will have to be exercised in instituting an examination into all possible causes for the occurrence of several consecutive cases apart from an origin by direct communication. It is quite possible that sometimes an entirely different explanation may be arrived at. He remarked that in Dr. Graham's cases the consolidation was patchy. This is quite exceptional in ordinary lobar pneumonia, although frequently seen in septic cases. The relation of this disease, as well as others, to a microscopic organism is as yet by no means positively determined. Culture experiments afford very strong evidence of the bacteria being the real originators of the disease, but there remain still some debatable points which must be overcome before the doctrine can be considered definitely entertained.

Dr. George Ross said that, although seeing a large number of cases of pneumonia every year, he had not met with any such series of cases as necessarily suggested the association of the latter of these with the first by contagion. He knew of Dr. Wilkins's cases alluded to by the reader of the paper, and admitted that they gave support to the idea of contagion. It seemed to him that the extreme rarity of any such groups of cases tended to preclude the possibility of such a common disorder being contagious. If this arose from special surroundings, was it not singular that with hundreds of such cases passing before us, it should be the lot of only one physician at long intervals to meet with examples of its propagation in this way? What peculiar conditions can we think of which would act in this way? If ever contagious, should not this property be manifested oftener? He would rather be disposed to consider that in these localized outbreaks we are really dealing with an affection differing in some essential way, as yet unknown, from the common lobar pneumonia.

Dr. Gardiner, of London, had met with a series in one family which seemed to fall within the category of the contagious. The first patient, aged twenty, contracted pneumonia. The mother suffered from chronic bronchitis. She soon fell ill with the pulmonary inflammation. A third member of the family and a grandchild sleeping in the same room were both prostrated by pneumonia within a few days. The only other possible explanation seemed to be a very strong family tendency acted upon by an exciting condition to which all were equally exposed.

Dr. Foster, of Portland, Me., said that in 1872 they had an epidemic of pneumonia in Portland. A singular feature which he had observed in these cases was that in nine out of ten cases the consolidation affected the apex of the left lung. In about one month they had probably fifty such cases. The course of the disease was unlike ordinary pneumonia, and also unlike typhoid fever. In one locality twenty cases occurred. As Medical Health Officer, he was called upon to investigate the occurrence. On tasting the water supplied there, he found a disagreeable flavor, reminding one of clam-water. He found that this water was supplied to the greater part of the infected district and came from a deep well, being clear and cold. About ten rods above the well were a row of privies,—a main sewer leading from these was traced, and found to have burst and caused the entire soil intervening between it and the well to have become infiltrated with foul matters. The sanitary defects were immediately remedied, the use of the water forbidden, and the outbreak at once ceased. Another endemic he had witnessed also bore upon this discussion. A young boy died of pneumonia in the almshouse after an illness of only two days. Within forty-eight hours they had thirty cases, the consolidation involving either the whole lung or spots in the lung. He found that extensive repairs had been made in the sewerage and pipe-system of the establishment and to this he attributed the outbreak. The cases were treated by an emeto-cathartic at the outset, followed by iron and quinine, and no more cases were lost. He looked upon cases of this kind as being of the nature of some peculiar lung disorder, resulting from blood-poisoning. He has been thirty years in practice and has never seen a case of pneumonia which he had even suspected of being originated by contagion. During the outbreak he had noticed that the nurses and attendants were never attacked.

Dr. Cassidy, of Toronto, remarked that the true etiology of pneumonia is still very obscure. It occurrs alike in the houses of the rich and in the poorest hovels. Wherever contagion is thought of we must beware of coincidence which may mislead oftener than we think. The general causes predisposing to pneumonia are of great importance to the sanitarian, because they are remediable. It has been observed in armies that the men in the barracks have sometimes suffered a large mortality from pneumonia, whilst those in the open air have entirely, or almost entirely, escaped, and when removing from close barracks to open tents, the disease had completely ceased.

Dr. Graham, in reply, said that the patchy character of the consolidation did not apply in his first case. He would admit in his series a difference of type, but no pathological difference. The doctrine of the unity of

pneumonia receives strong support. Sternberg has found the same parasite in normal saliva as in malignant erysipelas and in pneumonia. If so, the disease is determined not so much by the parasite as by the soil in which it grows. Dr. Graham would still look upon all the pneumonic cases as belonging to the same disease—the first case of a series being an ordinary pneumonia, other cases following it simply because the *materies morbi* finds unusually suitable soil in which to propagate and increase. Those who have experience with the work of developing cultures in the laboratory know that it is a very difficult matter to find a soil upon which certain bacteria will grow at all. An example of this might be given in the microörganism of chloasma, the microsporon furfur. Dr. Klein searched a long time for a congenial soil, all the commonly employed substances turning out failures. Many bacteria also permit of only a very narrow range of temperature. If this vary within 5° F. they die. The question, "What is the cause of ordinary pneumonia?" yet remains unanswered. A predisposing condition of the system is no doubt necessary. In Dr. Foster's cases, the polluted water may have so disturbed the system of those using it as to play the part of a predisposing cause.

Dr. J. H. Gardiner, of London, then read a paper on

THE INHIBITION OF THE HEART IN DIPHTHERIA.

The striking features of the cases related were the marked slowing of the pulse, followed, in two instances, by fatal syncope.

Dr. Graham had no doubt that the heart failure here was due to a poison acting upon the nervous centres. Recent discoveries pointed to the development of poisonous substances in ways not yet thought of, as, *e. g.*, in normal urine, and in the formation of ptomaines. In diphtheria, poisons may form and be absorbed. It is quite possible that even in tetanus, which was alluded to by the writer as opposed to this view, the same thing might occur. In some way not yet understood, a peculiar chemical substance might be produced, having an attraction for the spinal cord, and acting as an irritant upon it.

Dr. George Ross said that the theory last mentioned seemed the one best calculated to explain the occurrences. He would, however, caution against always attributing a sudden syncope after diphtheria to a central impression. When preceded by inhibitory symptoms, as in Dr. Gardiner's cases, there appeared no reason to doubt this explanation, but he had met with sudden fatality during the convalescence from this disease, where the autopsy showed clearly that the destructive change consisted in extreme fatty degeneration of the heart. Here there had, however, been no symptoms whatever, the pulse remaining at the normal rate. The possible existence of this structural change was another reason why every precaution should be taken during the period of convalescence.

Thursday, August 19.—Second Day.

Dr. F. W. Campbell read a paper on

THE TREATMENT OF WHOOPING-COUGH BY QUININE.

He spoke of the unsatisfactory character of the treatment usually adopted, and stated that a severe case of the disease in his own family had specially directed his attention to it. He referred to a paper by Dr. Dawson, Professor of Diseases of Children in the University of New York, on the quinine treatment of whooping-cough, which appeared in the *Canada Medical Record* for July, 1873, also to one by Professor Binz, of the University of Bonn, on the same subject, which was published in 1870. The authors of these papers considered pertussis as a neurosis of the pneumogastric nerve, caused by irritating and infectious mucus that accumulates in the pharynx and larynx. In this mucus was found a fungus, on which quinine had a specific action. Quinine also increased the secretion from the buccal and salivary glands, and thus assisted very materially in loosening the tenacious mucus from the pharynx. Dr. Campbell stated that in his hands the quinine treatment had been most successful, and that he now had notes of over one hundred cases of this disease treated in this way, with most satisfactory results. For children of three years and under, he gave it in doses of half a grain every two or three hours, and proportionately in larger doses up to twelve years of age, when two grains might be given. It should be administered in solution, and *no* sweetening should be added to disguise the taste.

Dr. Sherman, of Ogdensburg, New York, said he had used quinine in whooping-cough with excellent results. He considered it the very best treatment. He had, however, used sweetening to disguise the taste, and judging from results, saw no objection to it.

Dr. Macfarlane, of Toronto, said he had seen an article by Dr. Campbell on this subject a few years ago. Since then he had used quinine in pertussis, and had had excellent results.

Dr. Graham, of Toronto, had employed quinine extensively in pertussis, and could endorse most heartily Dr. Campbell's good opinion of it. Sometimes he had combined it with tannin. So far as his experience went, he saw no objection to the sweetening of the quinine mixture.

Dr. Campbell, in reply, stated that Dr. Dawson very strongly objected to any disguising of the bitter taste of the quinine. He had followed the directions in this respect, and was satisfied that they were correct. In fact, he was strongly of the opinion that even the appetizing effect of quinine is much interfered with by the addition of any syrup.

Adjourned.

CORRESPONDENCE.

GYNECOLOGICAL OPERATORS IN GERMANY.

The great rapidity with which pelvic surgery has advanced within the past few years, and the very varying successes of different operators, have tended to develop marked individual traits, and, in a large measure, to accumulate much of the material in the hands of a certain few men. In no country are there to be found, at the present date, so many well-trained scientific gynecologists as in Germany, and it is to the writer a very pleasant task to record some of the experiences which he has had, owing to the courtesies of three of the leading operators in that land. Through the extreme kindness of Dr. M. Sänger, of Leipzig, and the courteous attention extended to the writer by Prof. Carl Schröder and Dr. A. Martin, of Berlin, every possible facility for following their work was afforded.

It is hardly necessary to remark that Schröder, Martin, and Sänger are men of genius, and that every movement of theirs in connection with their work has a definite purpose, and a fitness peculiarly pleasing to the trained gynecological eye. The methods of Professor Schröder and Dr. Sänger are in most respects similar, and are characterized throughout by extreme care and attention to details, by deliberation in operating, by fertility of expediency, and a quiet certainty, inspiring universal confidence in the extent of their resources.

A brief description of Prof. Schröder's work will, then, to all practical purposes, describe that of Dr. Sänger. Upon requesting an invitation to the Frauenklinik, a card is given to the visitor, with printed conditions of his visits: That he shall not have seen any contagious cases, or come into contact with any infectious material within forty-eight hours; that he shall bathe, and come to the operating-room in clean linen. Ten or fifteen spectators are usually present, besides five assistants. The visitors are usually notified of the operation by postal card the day before, and at seven or eight o'clock in the morning the operation begins.

The Frauenklinik is situated in the heart of Berlin, on the banks of the Spree, and is, like many other medical and scientific institutions under imperial patronage, palatial in all its appointments. Among the visitors assembled in the waiting-room on the first floor are to be found doctors from the East and West of America: an active bright surgeon connected with the St. Louis Polyclinic; two of our brightest female practitioners in the East, who have bravely fought down every obstacle in their determination to see good work; doctors from the schools in France and Italy, from Chili, Japan, Holland, and from other parts of Germany; Dr. Küstner, of Moscow, a pupil of Pirogoff, and the translator of the Russian edition of Sims's *Uterine Surgery;* and Dr. Muchertschiansk, of Tiflis, in Georgia, well known through his valuable contributions to the *Wiener medicinische Wochenschrift.* The latter had been the assistant to Martin, the father, fifteen years before. The operating-room is on the second floor, well lighted from the whole western side, with painted walls, a very high ceiling, and a smooth stucco floor. A row of stationary stone washstands on one side of the room, and a long table holding solutions of bichloride and carbolic acid, bandages, iodoform, and dishes complete the furniture.

The patient lies on an iron frame table, the assistant dropping chloroform on a small flannel cap covering mouth and nose, while another usually has his hand on the pulse. Professor Schröder is at the patient's left side, while Dr. Hofmeier, usually his immediate assistant, and already well known by his writings, stands opposite, ready to sponge, control the abdominal walls, and render such other aid as may be required.

Consistent with the present status of antiseptic surgery, and bacteriological science in Germany—that is, with the positive convictions of the German surgeons that pyæmia, erysipelas, septicæmia, and probably all forms of suppuration, even the simplest, result from the intrusion of organic impurities upon the field of operation, and the development there of certain specific, more or less toxic properties—in consistence with this view, the most elaborate and important measures have all been taken *before* the operation has begun, and the keynote to the whole may be found included in the instructions to visitors—the intention is *not so much to war with germs during the operation, as to perform an operation upon a field where no germs are present.* Under these conditions, then, weaker germicidal solutions are used during the operation, solutions which, while powerless to destroy virulent germs in any numbers, yet destroy the few, and have been shown to exert a checking action upon their growth.

A strong spray has been playing for hours in the room; clothing, instruments, hands, and sponges have been thoroughly disinfected (heat is a favorite method for disinfecting instruments); the patient has had repeated baths; and now, just before operating, Dr. Hofmeier, with a large sponge and soap, most thoroughly washes the abdomen, thighs, and genitals, and follows this with a free douching and a solution of corrosive sublimate, 1 : 1000. Thus all is clean—"*peinlich*" and "*pilz-rein.*" The spectators group themselves around the foot of the operating-table, with their backs to the light, and follow Professor Schröder's movements as, with a few rapid strokes, he lays open the abdominal walls down to the peritoneum, and, without stopping to clamp superficial vessels, with a few light touches with the point of the scalpel, or by pinching up and nicking the peritoneum, lays open the abdominal cavity. The grooved director is never used, and a dissection of layers is never attempted.

If the tumor is an ovarian cyst, of but a few pounds in weight, it is turned out whole, and the base quickly tied off and seared; the larger vessels in the stump are again tied separately, and the operation completed in about twenty minutes. If the cyst be large it is freely incised, and emptied by rolling the patient over on her side. The sac is then turned out of the incision and adhesions discovered, cautiously separated, and all bleeding points either cauterized or ligated. There is no fear of using too many of the properly prepared fine silk ligatures. One case presented extensive dense pelvic adhesions, and the writer felt here an especial interest in observing the technique. Although eminent authority has declared that "ovariotomy is now a closed chapter," we may hope that, so long as the leading operators differ so markedly in their methods, and the percentage mortality still ranges in the tens, and, above all, our resources in dealing with the most formidable complication, pelvic adhesions, continue to be limited to enucleation, and the slow, dangerous, and often incomplete process of tearing loose and tying, we may at least hope for a *future appendix* to the chapter. In tying broad surfaces, where many would throw one ligature around the whole, or at most transfix and tie, Professor Schröder used many ligatures, and afterward secured by ligation such large vessels as could be discovered in the stump, such is the extreme care to prevent retraction and hemorrhage.

After a careful but not elaborate or prolonged toilet, the incision is closed by stout silk sutures placed an inch apart, with a superficial skin suture alternating. Iodoform is then powdered freely over the wound, and the dressing completed by a piece of rubber gauze, absorbent cotton, and a bandage.

It is impossible to characterize either Professor Schröder's or Dr. Sänger's work by any marked peculiarities. To a trained eye the use of the instruments, the quick

touch, the quiet confidence begotten of experience, speak volumes.

Dr. August Martin, on the other hand, while enjoying a reputation for skill and genius equally great, has strong personal peculiarities connected with every step of his work, which at once impress the most superficial observer.

Although not connected with any public institution for teaching, Dr. Martin forms private classes of instruction every few weeks into which most of those not making flying visits are admitted, and are afforded all the vast clinical facilities of his private hospital, and in addition are thoroughly instructed in minor gynecological operations practised upon Winckel's phantoms, in which actual parts—vulva, anus, and pelvic viscera have been skilfully inserted. Dr. Martin's hour for operating is eleven in the morning or twelve noon, and he invariably waits to perform three or four laparotomies at one sitting. Visitors stay down stairs until called by an assistant, they then file up to a special room, where coat, vest, and suspenders are removed, and they enter the operating-room in their shirt sleeves.

The operating-room is small, dingy, and narrow, smelling powerfully of carbolic acid spray. The patient lies at its further end under the window, supported from buttocks to head on a low galvanized iron table, the anæsthetizer and an assistant at the head; behind these the two fair American doctors, and grouped in a crescent on the patient's left the other spectators. Dr. Orthmann or Dr. Czempin are seated on the left assisting, and opposite is Frau Horn, a personage of more than local repute. Dr. Martin sits on a low wooden stool at the foot of the table and directly in front of the patient, whose legs hang over its edges. Dr. Martin and the assistants wear rubber shoes, and the spectators usually stand on a very wet floor throughout the operations.

No description of Dr. Martin's work would approach completeness without some account of his head nurse—Frau Horn. Originally associated for one or two years with Professor Schröder, she has for many years past identified all her interests with Dr. Martin. She is a woman of about middle age, stout, very quick, and with a bright, pleasant face. She makes every preparation for the operations, often takes entire charge of difficult cases in Dr. Martin's absence, and at an operation lends an assistance equal to any I have ever seen at the hands of the best trained hospital resident. She always anticipates the surgeon's wants, and he finds knife, scissors, or needle-holder in his hand without the delay of asking for them. She takes an intelligent interest in every step of the operation, which, in view of the valuable assistance she is rendering, is not obtrusive. She possesses, in fact, all the qualifications so desirable in a chief nurse, a woman all but a surgeon, yet content to remain a nurse. Her notions of absolute cleanliness are as rigid as those of Dr. Martin himself. On one occasion, during my stay in Berlin, a restless patient ruptured the stitches in the abdominal wound in the night and the bowel protruded. Frau Horn carefully cleansed and returned the intestine, reintroduced the stitches and redressed the wound.

She invented both operating and examining tables used by Dr. Martin, as well as the two curious instruments which he figures in his book, and uses in anterior colporrhaphy and perinæauxesis—the broad-ended knife and the comb.

The same careful preliminaries are observed here as at the Frauenklinik. Dr. Martin begins his work seated between the patient's thighs, and holding his knife like a pen, opens down to the peritoneum with a few bold sweeping strokes, and nicking this and slitting it up on the finger, within a minute the abdomen is open, the hand introduced and he is grasping the tumor. If the tumor be of a simple nature, it is quickly rolled out and the operation completed. The visitors then retire to await the next summons, and often another, and still another.

Frau Horn says "Dr. Martin is a true artist in his work," and, indeed, in his use of the knife, and his wonderful skill and certainty in introducing sutures in deep, almost impossible places, and by his general rapidity and assurance, he certainly justifies the assertion. In some cases, which in other hands would prove very tedious or even impossible, his methods are very remarkable, and even at times startling. Tumors fixed in the pelvis by adhesions, impacted myomata, and tubes and ovaries matted in old and recent exudates, are grasped and dragged out with the exercise of great strength, and they often yield with suddenness, producing a great suction sound which is alarming. If the field is in the least impeded by the intestines, they are all turned out and held in a towel, as originally practised by Dr. Martin's father.

In cases of hysterectomy, of which the writer saw a number, the tumor was lifted well up, and the lowest part of the uterus which could be reached firmly grasped by an elastic ligature. Deep lateral ligatures controlled the uterine arteries. The tumor was then shelled out, and the uterus split down to within a short distance of the ligature, the two sides were then amputated so as to leave a funnel-shaped hole in the cervix, which was scraped out, disinfected, and closed by three stages of continued sutures. When completed and dropped, the stump, always intraperitoneal, presented the appearance of a purse puckered across the top, with the line of sutures in the coronal axis of the body. When any considerable bleeding occurred sponges were packed into the pelvis, the operation continued, and the bleeding points caught and tied afterward.

Both Dr. Martin and Professor Schröder opened cases of cancerous disease, in which there was nothing to do but close the incision immediately. The former also opened two cases of tubercular peritonitis which were closed at once. These operations occurring once or twice weekly, it would often be possible to see seven laparotomies in one day, as both operators prefer waiting until there is more than one case to operate upon.

The facilities for seeing surgical, and especially gynecological, work in Berlin are not surpassed, and, I believe, scarcely equalled in any other city in the world.

Beginning with Professor Schröder's operations at seven in the morning, followed always by an admirable practical discourse, which is often replaced by operative midwifery, in the Entbindungs Anstalt, and Professor Bardeleben's clinic at the Charité at ten, and at eleven Dr. Hahn's clinic at the Friederich-Hain, in a room with most perfect equipments, and at eleven or twelve Dr. Martin's operations, in the afternoon. Again, the visitor is always sure of seeing major operations at Professor Bergmann's clinic, at the Kœnigliches Klinikum,

and at five can attend Professor Gusserow's admirable course at the Charité.

The trouble is not in finding occupation but in disposing of an *embarras de richesse*, and for the most advanced scientific work, for facilities, for courtesy, and, for what is not unimportant to many, good and cheap living, my advice is "go to Berlin."

Howard A. Kelly.

Edinburgh, August 2, 1886.

POISONING BY CASTOR-OIL BEAN.

To the Editor of The Medical News,

Sir: It is a fact probably not generally known, even to the profession, that the seeds or beans of the "castor-oil plant" (*ricinus communis*), quite commonly grown in gardens for ornamental purposes, are actively poisonous. The knowledge of the familiar oil expressed from them naturally induces the idea that the beans have similar medicinal properties and are equally harmless, but it is evident from the effects which they produce when taken internally that they contain other much more powerful constituents than the oil. This is true also of the cotton-seed. Cotton-seed oil is a perfectly bland oil, frequently sold as "sweet oil," and now largely exported from New Orleans to Italy, to be thence imported into this country as "fine olive oil." Yet an infusion of the seeds is, I am informed, a popular remedy in the South against intermittents.

Numerous fatal cases of poisoning by castor-oil beans have been reported, and three of them are said, upon good authority, to have caused death in an adult. A serious, though fortunately not fatal case, in which twelve or fourteen of the beans were eaten by a middle-aged woman for the relief of obstinate constipation, occurring recently in my own practice, has led me to ask the use of your columns to call attention to the danger of allowing the beans to be eaten carelessly or ignorantly.

Yours respectfully,

Edwin H. Bidwell, M.D.

Vineland, N. J.

NEW INVENTIONS.

A NEW SERIES OF BERLIN WOOLS FOR THE SCIENTIFIC DETECTION OF SUB-NORMAL COLOR-PERCEPTION (COLOR-BLINDNESS.)

By CHARLES A. OLIVER, M.D.,

one of the ophthalmic and aural surgeons to st. mary's hospital, philadelphia, etc.

Believing that Holmgren's method for the detection of color-blindness is the best, I have devised a new series of loose wools in an endeavor to place his plan upon a more substantial basis. In this set there are three series of colors:

1. Five principal test-skeins. These are pure colors. Latin names are employed to represent them. They are made of equal intensities, and are not designated except by being made of large size.

2. A series of twenty small pure match skeins. Each skein is either a pure tint or a pure shade of one of the large skeins, and has a black bangle containing lettering fastened to it; the inscription indicating that the skein is either a certain tint or shade.

3. A series of seventy-two small confusion match skeins. Each skein contains a mixture of certain percentages of light and shade of two of the large skeins. Each has a bangle which shows that is of such a character.

The wools are to be wrapped in black muslin, and will be enclosed in a black box, which will also contain an explanatory sheet with the colors arranged in their proper order, together with a book of instructions and a spectacle frame with a movable stop.

In addition to the good qualities possessed by the Holmgren wools, the following special advantages can be claimed for the new system:

1. *Five principal tests.* Pure blue and pure yellow have been added.[1] This has been done because both of these pigments serve as useful tests in the detection of the barely perceptible changes in color-sense which occur in the incipient stages of optic nerve disease.

2. *The wools are loose and separate.* By this the candidate has the entire mass of color from which to select, and there is nothing by which judgment as to plan can be brought into play.

3. *The colors are all of equal relative intensity.* This makes the selection a question of color choice alone; any interference to accuracy being avoided by keeping free from the power of skilful shading possessed by the "color-blind."

4. *Each skein has its value expressed.* Every skein becomes a unit of worth, and is related to every other skein. This has been done by the selection of colors of relative intensities, and by the use of a system of bangles which is incomprehensible to all but the initiated.

5. *It can be employed by any educated layman.* By means of the bangles the registry of the choice is easy for anyone who has been made acquainted with the method. A report of the selection can be copied upon a printed form, which can be sent to any authoritative person by whom it can be studied, and the color-sense of the examinate properly and fully determined.

6. *Accurate notings of passing color-changes can be preserved for future comparison.* This is of importance in furnishing means by which more accurate study of disease can be made, better notions of prognosis given, and more useful plans of therapeutics applied.

7. *Written and verbal expression of the character and amount of subnormal color-perception can be given.* This will afford the reader of any article or hearer of any paper upon this subject, more exact data in reference to the nature and degree of the color-changes noted. The vague terms now employed can be discontinued, and expressions like those used for the acuity of vision, etc., substituted.

8. *All the wools are of the same grade of manufacture.* This destroys, in measure, any argument against the employment of this material in color-testing, because here the chances for selection, by the use of touch, are greatly lessened.

9. *All the colors are from vegetable dyes.*[2] By this,

[1] The rose (purple) test of this series has more red in it than is found in this sample among Holmgren's wools. This has been done so as to get all of the principal test-skeins of the same degree of saturation and intensity.

[2] Some of the dyes of the present invoice are not vegetable in character, although they have been employed because differentiation by the sense of touch is impossible upon account of the equal

any error that might arise from harshness of color-surface allowing detection by the sense of touch is avoided. Besides, such colors are more lasting to light exposure, and not so subject to the objection of possessing odor.

10. *The use of a black surface in testing.* Here there is nothing but a display of color. Contrast is avoided, and any chance for the formation of subjective after-colors lessened.

11. *Any order of testing may be pursued.* This is done by naming the tests, so that any color may be taken first.

12. *Quantitative determination as well as qualitative determination obtained at one sitting.* This has not been accomplished by any other method.

This series of wools were exhibited at the late meeting of the American Ophthalmological Society. James W. Queen & Co., of Philadelphia, have gone to considerable expense and difficulty in having all of the wools imported from a large European house. Sets will be ready in a short time.

1507 Locust Street.

NEWS ITEMS.

The Manufacture of Quinine by Synthesis.—According to the *Lancet*, a remarkable discovery, by which the price of quinine may be reduced to something like 3*d.* per ounce, has been made by Mr. Cresswell Hewett. The synthetical manufacture of quinine was first suggested to Mr. Hewett in 1869 by the late Dr. Mattheson, of St. Bartholomew's Hospital, whilst giving his assistance in a course of experiments in connection with apomorphia. Subsequently, Prof. Parkes, of Netley, aided with his advice, and to these gentlemen, rather than to himself, Mr. Hewett modestly explains that the process is due. The importance of this discovery is rendered greater by the fact that while hitherto we have been depending for our quinine on the cultivation of the cinchona tree, from the bark of which only about two per cent. of good quinine can be extracted, ninety-eight per cent. being valueless, the drug can now be manufactured without limit by a very simple process from an article which can always be got in abundance in any part of the world.

Death from Bromidia.—A telegram to the Austin *Statesman*, from Waco, Texas, announces the death on July 6th, at the latter place, of Dr. Joseph Willis from an overdose of bromidia, taken for the relief of pain. The Texas *Medical Journal* speaks in very high terms of the deceased, who although only thirty-eight years old, had been for several years a prominent member of the Texas State Medical Association.

Food Inspection in Ohio.—A law has been enacted in Ohio creating the office of dairy and food commissioner. His duty is to inspect any article—butter, cheese, lard, syrup, sugar, or other articles of food and drink—and to prosecute corporations, firms, or persons engaged in the manufacture or sale of any adulterated or counterfeit article of food or drink in violation of the laws of Ohio.

Sir William Stokes, of Dublin.—A Dublin correspondent of *The Lancet* writes: "The numerous friends of the President of the Royal College of Surgeons in Ireland will be gratified to learn that he has received the honor of knighthood at the hands of his Excellency the Lord-Lieutenant. Sir William Stokes is an able exponent of Irish surgery, a gentleman of high professional eminence, and possessed of abilities of no mean order. A clever writer, an eloquent speaker, and an honorable gentleman, Sir William holds a foremost place in professional circles in Dublin. The only regret that can be felt is that the higher dignity was not conferred upon a gentleman who holds the highest position the Fellows of the Royal College of Surgeons could bestow upon him. It cannot be denied that successive Governments have dealt very shabbily with the medical profession in Ireland, and it is to be hoped—although from the past little can be expected—that the new Government may see their way to reward the profession in Ireland as in other portions of the United Kingdom."

Prof. Langenbeck has just undergone an operation for cataract at the hands of Dr. Pagenstecher, and was dismissed from the clinic, perfectly cured, at the end of eleven days.

Professor Bouchard has been elected member of the Académie de Médecine.

A Munificent Gratuity.—A gratuity of £10,000 has been granted from the Bavarian Civil List to the widow of Prof. von Guden, of Munich, who perished with the late King of Bavaria in the lake at Castle Berg. He left a family of eleven children.

Tea-drinkers' Diseases.—It is not a little curious that the diseases arising from the wrong use of tea should be met with in greater frequency in countries foreign to its growth. It might have been supposed that where production went on there would be found those evils that attend the consumption of tea in their greatest extent; but such does not appear to be the case. The diseases due to tea are well known to physicians, but the public seem to be strangely indifferent to the teachings of their medical advisers in these matters. Recently in France, M. Eloy has reminded medical men how vast is the number of diseases owning an allegiance to the dominion of Queen Tea. The list of headings in M. Eloy's paper is well calculated to arouse attention, and, we hope, to lead to some abatement of this widespread disorder. America and England are the two countries that are afflicted most with the maladies arising from the excessive consumption of tea. Individuals may suffer in a variety of ways. It is customary to speak of acute, subacute, and chronic "theism"—a form that has no connection with theological matters. It is possible to be a "theic" by profession or a "theic" by passion. The predominance of nervous symptoms is a characteristic of theism; general excitation of the functions of the nervous system may be observed; or the weakness may be noted more especially in the brain as distinguished from the spinal

intensities. In order to avoid any error whatever, attention will be paid to this question in all future selections.

I shall be pleased to assist anyone in obtaining the proper selection of wools, and to give all necessary information in reference to their manufacture.

cord. Perversion of the sense of hearing is not at all an uncommon symptom—patients hearing voices that have no real or objective existence. The irritability that overtakes women so frequently may sometimes be clearly traced to an excessive indulgence in afternoon tea. It is a mistake to suppose that it is the poor sempstress who is the chief sufferer from theism. No doubt the tannin which tea that has been standing long contains does a great amount of mischief, but the derangement that it causes hardly belongs to that class of diseases with which we are at present concerned. Rather does theism belong to that genus of disease in which morphinism, caffeism, and vanillism are found. The habit of tea-drinking is one that grows on its victims like the similar ones of opium or alcohol. Taken in strict moderation, and with due precautions in the mode of preparation, tea is, like alcohol, a valuable stimulant; in its abuse there is also a certain analogy. There is hardly a morbid symptom which may not be traceable to tea as its cause. This is a fact that general practitioners often use to their own satisfaction and to their patient's advantage, if it happen to be that kind of patient who does not object to make some sacrifice in order to be rid of troubles.—*Lancet*, July 3, 1886.

Cholera in Japan.—News comes from Japan that the cholera epidemic there becomes more and more intense. Strangers, and the Japanese in good circumstances, are not suffering much from its attacks, but the poor native population is almost decimated.

Irregular Schools.—The following is a list of colleges, the diplomas of which will not be recognized by the Iowa State Board of Health:

American Eclectic College, Cincinnati; American Health College, Cincinnati; American University of Pennsylvania (Buchanan), Philadelphia; Beach Medical Institute, Indianapolis; Bellevue Medical College of Massachusetts; College of Physicians and Surgeons, Buffalo, N. Y.; College of Physicians and Surgeons, Milwaukee; Eclectic Medical College of Philadelphia; Edinburgh University, Chicago and St. Louis; Excelsior Medical College, Boston; Hygeo-Therapeutic College, Bergen Heights, N. J.; Hygeo-Therapeutic College, New York City; Joplin Medical College, Joplin, Missouri; Livingston University, Haddonfield, N. J.; Medical Department of the American University of Boston, Boston; New England University of Arts and Sciences, Boston; New England University of Arts and Sciences, Manchester, N. H.; Penn Medical University, Philadelphia; Philadelphia University of Medicine and Surgery, Philadelphia; Physio-Eclectic Medical College and Physio-Medical College, Cincinnati; St. Louis Eclectic Medical College, St. Louis; St. Louis Homœopathic Medical College, St. Louis; Curtis Physio-Medical Institute, Marion, Indiana; American Anthropological University of St. Louis; Medical Department of Drake University, Des Moines, Iowa; and King Eclectic Medical College, Des Moines, Iowa.—*Iowa State Medical Reporter.*

Examination of the Royal College of Surgeons of England.—The following questions were submitted to the candidates at the recent final examination for the diploma of Member: *Surgical Anatomy and the Principles and Practice of Surgery.* (Candidates were required to answer at least four (including one of the first two) of the six questions, and were strongly advised to answer all six questions.) 1. Give the relations of the femoral artery in the middle of the thigh, and describe the operation for applying a ligature for punctured wound at that part. 2. Describe the position and attachments of the omohyoid muscle. State fully its relations to the larger vessels of the neck, and its use as a guide to the operator. 3. What is an intussusception of the bowel? Give its causes, diagnosis, and treatment. 4. Give the differential diagnosis of ascites, ovarian tumor, and pregnancy. Describe the operation of ovariotomy. 5. Give the signs of a dislocation of the radius and ulna backward. What structures would resist reduction? How would you reduce the dislocation, and in what position would you put the limb afterward? 6. How would you diagnosticate an acute inflammation of the middle ear? What are the dangers of such a case? Describe its treatment. *Midwifery and Diseases of Women.* (Candidates were required to answer three of the four questions.) 1. How would you distinguish between a face and breech presenting? Describe the management of labor when the breech presents. 2. How would you treat a case of partial placenta prævia when the os uteri is dilated to the size of half a crown and hemorrhage is present? 3. What is puerperal eclampsia? What are the pathological conditions with which it is associated? How would you treat a case (1) before the attack, (2) during the attack? 4. What is pelvic hæmatocele? What are the conditions for which it may be mistaken, and how would you make the diagnosis? *Principles and Practice of Medicine.* (Candidates were required to answer three of the four questions, including question No. 4.) 1. What are the causes, symptoms, sequelæ, diagnosis, and treatment of diphtheria when it affects the fauces and pharynx? 2. Describe the causes, appearances, and treatment of ringworm; give the prognosis and diagnosis. 3. What are the different kinds of hemiplegia, and how does each kind enable you to predicate the seat and nature of the lesion? 4. Give the composition, uses, and doses of cerii oxalis; injectio morphiæ hypodermica; liquor strychniæ; oleum terebinthinæ; pulvis ipecacuanhæ compositus; pulvis kino compositus; tinctura camphoræ composita; tinctura cannabis indicæ.

Medical School in Turkey.—Turkey has a medical school at Constantinople, at which there are annually more than three hundred students, of which number some sixty are graduated. Each course continues during nine months of the year, and six years must be spent in medical study before a diploma can be received. Instruction is given in the Turkish language, as most of the students are Turks.

Responsibility of Druggists.—A Montreal man lately sued a druggist for damages for having been deprived of work for several weeks in consequence of taking poison sold him by mistake. The error was caused by the wholesaler, who had labelled the package wrongly before selling it to the druggist. The court held, however, that the druggist should have verified the contents of the package, and gave judgment for two hundred dollars and costs.

A Professional Sinecure.—It is officially announced that Señor Rafael Alcalde y Buril has been appointed surgeon-dentist to the infant king of Spain, whose birth lately gave rise to so much rejoicing in the Spanish capital. The *Globo* inquires, very naturally, whether the young king was born with teeth. In any case, the post of this professor of the gentle dental art will, for some months to come, be as much a sinecure as that of the surgical instrument-maker who was recently addressed by a country customer as "suspensory bandage-maker to Her Majesty."—*British Medical Journal.*

Deaf-mutism in Spain.—According to Señor Don J. Lopez Navalon, Principal of the National College for Deaf-mutes in Madrid, the number of persons afflicted with deaf-mutism in Spain is more than 10,090. For these there are, beside the Madrid College, which is supported by the State, only four other institutions in the provinces, and these are all supported and managed by private enterprise.

Cremations at Père la Chaise.—Next month the Parisians will be able to burn their dead in four crematory furnaces, which have just been finished at Père la Chaise. These furnaces were begun last November, and have been hurried on to completion, so that by the end of August, at latest, those who, in dying, express the wish to be cremated can be there reduced to ashes. There will be no first, second, and third class cremations. Poor and rich will be on a footing of absolute equality. The price charged to those who can afford to pay for the burning of a corpse will be 15 f.—or say 12 s. The furnaces were constructed on plans by MM. Barrett and Formice. A large portico is in front of a dome, beneath which are placed the crematory furnaces. They have the appearance of very elegant ovens. Three hundred and fifty thousand francs is the price they cost. They are according to the Corini system, in use in Rome and Milan. It was found that the heat of the Siemens furnace was too intense. Instead of reducing the corpse to ashes, it subjected it to a kind of vitrification. The cost, too, would be 200 f., instead of 15 f., to cremate with a Siemens furnace. The unclaimed bodies at the hospitals which are not used for anatomical purposes will be taken to the crematory at Père la Chaise. Sculptors, goldsmiths, and bronze-casters are already busy designing urns, of which an assortment in marble, bronze, gold, silver, zinc, or lead will be kept at an office of the crematory. The relatives of the cremated dead can buy these vessels, and cause them to be removed to family vaults or to a building which the city of Paris is to erect. There could be no greater boon to a large city with overcrowded cemetries than the furnaces of Père la Chaise. I cannot conceive anything more disrespectful to the dead than the way their remains are treated here, even when a first-class burial can be provided, if there is not a family vault in which to place them. Buying a grave is no simple matter. The delays are endless, and the application for one must go through many bureaus before official consent is given. Then there are other formalities to be gone through. Meanwhile the corpse is in a charnel house, called a provisional vault, at a cost of 1 f. a day. The removal thence to the grave, which must be in masonry at the sides, is a cause of danger to the public health.—*London Daily News.*

The Vatican and Cremation.—The Roman Holy Office has issued a decree forbidding Roman Catholics to belong to cremation societies, and the practice of cremation is stigmatized as *detestabilem abusum corpora humani cremandi.*

Height and Weight.—Dr. Broca, the eminent anthropologist, is the author of a formula relative to the height and weight of the human body. It is that the body should weigh as many kilogrammes as it measures in centimetres, after deduction of the first metre. Thus, a man measuring one metre eighty centimetres should weigh eighty kilos. Should his weight be more or less, he is too stout or too thin. As men grow older they lose weight, but as a compensation they diminish in height also.

Indestructibility of Human Hair.—That human hair retains its characteristics for long periods of time, and, indeed, is well-nigh indestructible, is a fact of common observation. A remarkable instance of this is found in a wig which has recently been discovered in an Egyptian temple at Thebes, and is now deposited in the British Museum. It is supposed to have been part of the attire of an Egyptian priest, and from the circumstances of its discovery is regarded as being at least 3400 years old.

A Pair of Centenarians.—There has recently died in St. Petersburg Madame Goruli, a contemporary of the Empress Catherine II., and a lady of the court of the Emperor Paul I. She is stated to have been 114 years old. Among those who attended her funeral was her sister, who had attained the age of 113, but who was still so robust as to be able to follow the bier on foot.

Apparent Intoxication.—There is reason to fear, says the *Lancet*, that mistakes are not unfrequently made, even by skilled observers, in the recognition of drunkenness, by what may be called "apparent intoxication." The unsteady gait, the congested face and neck, the vacant eye, with drooping lid, and even the spiritous breath of apparent intoxication, may one and all be the effects of disease or disturbance of function, which has no necessary connection with the abuse of alcohol in any form. A melancholy instance of blundering in respect to this matter may be cited from the life of the late Colonel Herbinger, who, as our Paris correspondent mentioned last week, was accused of intemperance during his field service at Tonquin, but happily acquitted. Professor Peter, who had opportunities of studying the case of this recently deceased officer shortly before his death, elicited that he was suffering from a malady of some years' standing, which produced cerebral anæmia with such giddiness that he could scarcely sit on his horse. Similar cases are by no means uncommon, and while it is more than ever necessary to denounce the practice of permitting police officers to determine whether a man or woman is drunk or the victim of disease, it is requisite to go much further than this, and to call the special attention of skilled practitioners in medicine to the possibility of being mistaken by erroneous impressions on this subject. Not only will anæmia of the brain, however induced, cause giddiness, but certain forms of defective assimilation

will bring about the same results, together with symptoms still more deceptive. We need to study more closely the effects of an excess of oxalic acid in the blood, of accumulated uric acid, or urate of ammonium, of acetone, etc. Something has been done in this direction; but, so far as we are aware, the precise cause of a peculiarly offensive odor of the breath, expelled from the mouth, seemingly distinctly alcoholic, has not been satisfactorily made out, although several good clinical observers with a fair knowledge of the chemistry of digestion and elimination have undertaken to solve the problem. It would be useful to investigate the subject further; more light is desirable, and even necessary.

Priority in the Use of Potassium Iodide in Aneurism.—Duroziem points out, in *l' Union Médicale*, 1886, No. 44, that the credit for priority in using potassium iodide in aneurism is not due either to Chuckerbutty or to Balfour, as generally stated, but to Bouillaud. This observer published in the *Gazette des Hôpitaux*, for February 8, 1859, a paper entitled "Two cases of aneurism treated by iodide of potassium; gradual and complete disappearance of one, decided improvement in the other."

Necroptic Entomology.—In a discussion of medico-legal subjects at a recent meeting of the Académie de Médecine, M. Laboulbène said that entomology ought to render great service in tracing the probable length of time that a body had been dead. The *insectes necrophiles*, or carrion insects of the earlier decomposition, leave their prey in a regular order of succession. There comes a time, however, when the dry horny portions alone are left, and even these are attacked by the attagenes, anthrenes, and ptionioses, etc. in a certain definite order.

Dr. Charles D. Homans, of Boston, died at Bar Harbor, on the evening of Thursday, September 2d. Dr. Homans was born in Brookfield in 1826, and was educated at Harvard College, receiving his degree of B.A. in 1846, and of M.D. in 1849. His father, Dr. John Homans, was a noted physician in his time, and his grandfather was a surgeon at the battle of Bunker Hill. He was a member of the first surgical staff of the Boston City Hospital, and at the time of his death was the senior visiting surgeon to the institution. He was President of the Massachusetts Medical Society for two years, resigning only a few weeks ago, and at the time of his death he was President of the Massachusetts Humane Society.

Dr. Thomas A. McBride, of New York, died at sea on board of the North German Lloyd Steamship "Aller" on Tuesday, August 31st, aged forty years. He had been at Karlsbad during the summer for the benefit of his health, and seemed greatly improved until a few days previous to his departure from London, where he was taken ill. He recovered sufficiently to enable him to proceed to Southampton where he was able to board the "Aller." On the steamer everything possible was done for him by Captain Hammelman and Surgeon Norr, assisted by Dr. D. B. St. John Roosa, of New York, who was a fellow passenger. It was evident, however, by the following afternoon that he was conscious of his approaching death. After bidding good-bye to some friends who were with him, he relapsed into semi-consciousness, from which he did not rally. He was buried at sea at midnight on Tuesday. Dr. McBride was attending physician to the Presbyterian Hospital, and a well-known specialist in diseases of the nervous system.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 31 to September 6, 1886.

Middleton, P., *Major and Surgeon.*—Assigned to duty at St. Francis Barracks, St. Augustine, Fla., as Post-Surgeon.—*S. O. 126, Division of the Atlantic*, September 2, 1886.

La Garde, L. A., *Captain and Assistant Surgeon.*—Upon departure of Third Infantry from Fort Ellis, Montana Territory, to proceed to Camp Sheridan, Mammoth Hot Springs, Wyoming Territory, and report to the commanding officer for duty, relieving Assistant Surgeon Pilcher.—*S. O. 87, Department of Dakota*, August 27, 1886.

Crampton, L. W., *Captain and Assistant Surgeon.*—Relieved from further duty at Bellevue Rifle Range, and granted leave of absence for one month, to take effect before rejoining his proper station (Fort Bridger, Wyoming).—*S. O. 108, Department of the Platte*, August 28, 1886.

Pilcher, James E., *First Lieutenant and Assistant Surgeon.*—When relieved by Assistant Surgeon La Garde, from duty at Camp Sheridan, to return to his proper station (Fort Custer, Montana Territory).—*S. O. 87, Department of Dakota*, August 27, 1886.

Wood, L., *First Lieutenant and Assistant Surgeon* (recently appointed).—Ordered to report by letter to the Commanding General of the Department of Arizona, for assignment to duty.—*S. O. 202, A. G. O.*, August 31, 1886.

Mason, Chas. F., *First Lieutenant and Assistant Surgeon.*—Relieved from duty in the Department of the East and assigned to duty in the Department of Arizona.—*S. O. 203, A. G. O.*, September 1, 1886.

Walker, Freeman V., *First Lieutenant and Assistant Surgeon* (recently appointed).—To report in person to the Commanding General, Department of the East, for assignment to duty.—*S. O. 203, c. s., A. G. O.*

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending September 8, 1886.

Dickson, S. H., *Passed Assistant Surgeon.*—Detached from the Naval Academy, October 1, 1886, and ordered to Navy Yard, Washington.

Lippincott, J. G., *Passed Assistant Surgeon.*—Ordered to Naval Academy, October 1, 1886.

Shippen, E., *Medical Director.*—Detached from Naval Hospital, Philadelphia, Pa., and ordered to attend officers of the Navy and Marine Corps at Philadelphia not otherwise provided with medical aid.

Hord, Wm. T., *Medical Director.*—Detached from Examining and Retiring Boards at Washington, October 5th, and ordered to Naval Hospital, Philadelphia, Pa.

Dean, R. C., *Medical Director.*—Ordered to duty as a member of Examining and Retiring Boards at Washington, October 5, 1886.

Bransford, J. F., *Surgeon.*—Detached from U. S. S. "Iroquois," and ordered to Naval Hospital, New York.

Hall, C. H. H., *Passed Assistant Surgeon.*—Detached from Naval Hospital, New York, and ordered to Naval Hospital, Yokohama, per steamer of 21st inst.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine-Hospital Service, for the Three Weeks Ending September 4, 1886.

Bailhache, P. H., *Surgeon.*—To proceed to Cape Charles Quarantine, as Inspector, August 27, 1886.

Fessenden, C. S. D., *Surgeon.*—Granted leave of absence for thirty days, August 30, 1886.

Godfrey, John, *Surgeon.*—To proceed to Biloxi, Mississippi, and investigate alleged yellow fever cases, September 1, 1886.

Irwin, Fairfax, *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, September 2, 1886.

ORIGINAL LECTURES.

HELMINTHIASIS—TAPEWORMS.

A Lecture Delivered at the Medical College of Ohio.

BY JAMES T. WHITTAKER, M.D.

THE term helminthiasis, which was formerly used to express a peculiar dyscrasia, the so-called verminous crasis of the older writers, is limited in our day to signify simply the presence of mature worms (helminths, *ἑλίω*, I roll or twist) in the intestinal canal, or immature forms in the organs and tissues of the body. For it is now well established that parasites occur in the body, not by spontaneous generation, or as the expression of disease of the intestines, but only as the result of the ingestion of their eggs or embryos with the food and drink.

Of the whole number of known parasites of man, now in the neighborhood or fifty, twenty-one occupy the interior of the body as the so-called entozoa. Most of these forms are so rarely found as to constitute clinical curiosities, and many of them have never been observed in our country. In fact, but four varieties—the tapeworm, the round worm, the thread worm, and the trichina—are so commonly encountered as to demand especial study by the practitioner of medicine.

With the exception of the trichina, these parasites were known to the physicians of antiquity. Mention is made in the works of Hippocrates of the tapeworm (*ταινία*, a band), the round worm (*στρογγύλος*, round), and the thread worm or ascaris (*ασκάριζω*, I spring), forms which still retain their ancient names. But the most extravagant and erroneous views were entertained of them up to the middle of our own century. Thus Valisnieri believed them to be inherited, Gœtze and Abildgaard claimed that they assisted digestion by consuming the intestinal mucus, and exciting peristalsis, as the Abyssinians still believe, and Jördens went so far with these teleological conceits as to call them the guardian angels of childhood. On the other hand, intestinal worms were supposed to engender all kinds of diseases, and as late as the eighteenth century they were thought to produce scurvy, dysentery, and diabetes. Post-mortem examinations, which disclosed them, interpreted them as a cause instead of a coincidence of disease. Thus, Droste found on autopsy twenty-nine round worms as the cause of basilar meningitis, and Parkinson five tæniæ as the cause of incarceration of the bowels. Valisnieri describes how worms penetrate the vessels to reach the blood; and Waurach, as late as 1844, taught their origin from damp habitations, the excessive use of flour and potatoes, restraint of the emotions, abstinence from coitus, etc. Encysted worms were at this time universally believed to arise by spontaneous generation.

Existing knowledge of intestinal parasites begins with the observations and experiments of Siebold, Steinstrup, Küchenmeister, Davaine, and Leuckart, in 1840–60, which revealed the various metamorphoses and migrations of the egg, the larva, and the fully developed forms, often in different hosts. These changes of form are, however, no more to be considered as alternations of generation, as they are sometimes erroneously described, than are the changes from the ovum to the fœtus, and the mature form of man, which differ in the same or even greater degree.

The first recognition of a difference in the varieties of tapeworm was made by Felix Plater, in 1602, with the discovery of the bothriocephalus (*βοθρος*, a pit) latus, thus named by Rudolphi in 1810. To these forms was added a third, the tænia mediocanellata, or saginata, by Küchenmeister in 1852. The tænia echinococcus (*εχινος*, the hedge-hog) was first distinguished as a living thing by Pallas in 1760, and its scolices (*σκώλιος*, crooked) recognized as the tapeworm heads by Pastor Göze in 1782. Except in the case of the bothriocephalus latus, the larva of which has just been discovered by Braun, of Dorpat, the development of the larval into the mature form in all the varieties of tænia in man was demonstrated by the feeding experiments of Beneden, Siebold, Leuckart, and more especially Küchenmeister, who verified his observations on animals in the bodies of criminals which he was permitted to use.

The history of the trichina (*θριξ*, *τριχος*, a hair) is purely modern. Calcified remnants of this parasite in muscle were looked upon as dissecting-room curiosities up to 1835, when Pajet took a specimen to Owen, who gave it the name it bears. Leidy, in 1846, discovered in a piece of ham upon his plate the same immature form which was still regarded as an innocent, wandering, nematoid form until 1860, when Zenner discovered it in myriads in the muscles of a patient who had died of a disease diagnosticated as typhoid fever, but marked by extreme pain in the muscles, with œdema of the surface, which symptoms he correctly attributed to the presence of the parasites. Virchow, Leuckart, and Zenker then demonstrated their migration from the intestines to the muscles, and two years later, in 1862, Friedreich made the first diagnosis of the disease in life with the detection of the parasite in a piece of exsected muscle.

The difficulties encountered in the study of these parasites become apparent with the recognition of the difference of the host in the various stages of development. Thus the mature tænia saginata (fat) lives only in the small intestine of man, while its larva or cysticercus dwells in the muscular tissues of the ox. Möbius met it once in a giraffe confined in a zoölogical garden; and Zenker, Cobbold, and Heller bred it repeatedly in the goat and sheep. The mature tænia armata is also found only in the intestine of man; its larva or cysticercus in the flesh of the pig, dog, deer and polar bear (in confinement). The mature tænia echinococcus inhabits exclusively the small intestine of the dog and the wolf, while its larva, the echinococcus, is found in the

liver and various organs of man, the ape, ox, sheep, horse, hog, and many other animals. The mature bothriocephalus latus lives in man, and allied species in many fishes, while its larva infests the bodies of fresh water fish—the pike, trout, eel-pout, etc. The liver fluke, an occasional inhabitant of the liver of man, and much more frequently of the sheep, in which animal it constitutes the disease known as the "rot," lives in its immature form in the body of a fresh-water snail; and the trichina spiralis which occurs in both the mature and immature form in man, and in many other animals —the pig, rat, rabbit, cat, and fox, is received into the body of man by the ingestion of the immature form in pork. As a curiosity illustrative of the difficulty of detection of larval form at times, may be mentioned the case of the tænia elliptica, which in maturity inhabits the intestine of the dog, while its larva is found in the louse of the dog (Leidy).

Tapeworms (cestoides, κεστος, embroidered, a belt; ειδος, like).—Of the three hundred species of tæniæ in the whole animal kingdom, but four are found in the body of man, viz., in the order of frequency in our country, the tænia saginata, armata, echinococcus, and lata, or bothriocephalus latus, derived respectively from the ox, pig, dog, and fish.

The whole animal in its maturity consists of a head (scolex), a slender neck, which, at some distance from the head, shows transverse folds or wrinkles, deepening later or lower down into furrows, which indicate the separate segments (proglottides) of the body. The head of the tapeworm is oval, about the size of a pin's head, and is provided with two to four equidistant suckers about its upper surface. The segments four to twelve hundred and more in number are at first longer than broad, then in some cases quadrate, and finally broader than long. Upper are let into lower segments, and union is firm at first, but lax toward the end of the worm, where detachment easily occurs. New segments are produced from the neck, so that the last segment is always the last so long as it remains united to the rest. Hence the necessity of securing the extrusion of the head in the total extirpation of the worm. Each segment contains or is filled with the generative apparatus of both sexes; hence the animal is hermaphrodite. It is also self-impregnating. The bulk of the segment is taken up by the uterus, which forms an elongated central cavity, with radiating branches stuffed with eggs. The male element is comprised in a bunch of seminal vesicles which empty into a seminal duct, terminating at a pore in the lateral margin of the segment common to the uterine opening or vagina. These genital pores are disposed alternately, or on opposite sides of the different segments.

The tapeworm fastens itself by its suckers to the mucous membrane of the small intestine, the body floating free in loose folds or elongated along the course of the canal, from the contents of which it imbibes nutrition by osmosis. The contents of the large intestine will not support it. It is feebly endowed with motion, so that detached segments voided with feces may migrate by slow vermicular action a few feet from the seat of deposit. More extensive change of place is effected by outside agencies—running of water, processes of manuring, wandering animals, etc. Each segment may contain as many as 53,000 eggs, so that a tapeworm producing 800 ripe segments a year may furnish an annual contribution of 42,000,000 eggs. Fortunately, in the struggle for existence, myriads fail to find the necessary conditions; thus Leuckart calculates the chances of development of an egg to a cysticercus as 1 : 1340, and to a mature worm as 1 : 85,000,000. The tapeworm may live in the intestinal canal from ten to fifteen years.

The egg of the tapeworm is a rounded or ovoid body, provided with a thick envelope containing an embryo endowed with hooklets. Received into the body of an appropriate host, it is freed of its envelope by the action of the gastric juice, protrudes its head, and appears in the form of the larva. The larva is, of course, an undeveloped tapeworm. It has the same head and neck, much reduced in size, but the body remains a vesicle. It is always provided with hooklets, by means of which it bores its way through the walls of the stomach or intestine, to be lodged in adjacent structures or to be carried off by the lymph or blood current to distant organs, where it may excite a destructive inflammation or encysted, remain innocuous. The muscular structure of the body is the soil of predilection, and muscle thus affected is said to be "measly," from measle, a spot. In the course of three or four months the vesicle attains its full development, to the size of a large pea; a new head develops from its inner surface, and the larva becomes a cysticercus (κυστις, bladder; κερκος, a tail). The cysticercus lives, as a rule, from three to six years, when it perishes to undergo calcareous degeneration; but ingested during its life into the stomach of man, it attaches itself to the small intestine, reproduces segments which become sexually mature in the course of three or four months. Periods of quiescence usually occur in this regard. Bettelheim records a case in which no segments were given off in the space of three years. Ordinarily but one tapeworm is found in the body of man, yet abundant instances are recorded of the presence of two or more of the same or different varieties at the same time, or of their coincidence with other forms of intestinal worms. Beranger Feraud once found twelve in the body of one individual, and Kleefer, of Görlitz (*Deutsche Klinik*, 1853), records a case in which forty-one tæniæ were discharged with heads.

The different varieties of tapeworm may be readily distinguished. The tænia armata, or pork tapeworm, erroneously called solium, because less frequently found alone than any other form, is known by its coronet of 22–32 hooklets, whence its name, on the circular rostellum, of its head, which is likewise provided with four small circular suckers. Its segments number 750–825, becoming sexually mature at the 450th member, as recognized by the presence of the genital pore, so that the worm may reach a length of 7–10 feet. They are at first longer than broad, then quadrate, and finally extremely oblong, whence the synonym cucurbitina. They are rarely discharged, except at stool. The uterus consists of a median cavity, never quite reaching the upper or lower margins, with 7–12 lateral branches, radiating irregularly like the branches of a tree, hence dendritic. Its larva, the cysticercus cellulosa, provided with four suckers and six horns, is found in the tissues of the pig, dog, deer, rat, sheep, ape, and bear, as well as in man, in the liver, subcutaneous connective tissue, muscle, eye, and brain. Its circular ova contain also

six hooklets. The tænia armata is found wherever raw or half-cooked pork is used as food.

The tænia saginata, or beef tapeworm, erroneously called medio-canellata by its discoverer, the narrow cylindrical uterus having been mistaken for a median canal, sometimes still called lata, because of its breadth, is known by its greater thickness and breadth, whence its name. Its head is larger and more square, and being devoid of a rostellum and hornlets, more flat on the top. It has likewise four suckers (though there is of this species, as well as of the armata, a variety which has six). The whole worm, more especially the head, is rather darker from the presence of more pigment matter than the tænia armata. The neck is shorter and broader. It is larger than the tænia armata, its twelve hundred and more segments measuring from ten to fourteen feet. Each segment is broad and long, often one-half by one inch. The body of the uterus quite reaches the upper and lower margins of the segment. But it is more narrow than in the armata, and all its branches are finer. These lateral branches, more numerous than in the tænia armata, fifteen to twenty-seven on the side of the genital pore, thirty-one on the opposite side, are always given off dichotomously. The segments are voided, not only at stool, but often also spontaneously. Patients who are continually or occasionally discovering detached fragments in their clothes are nearly always hosts of the tænia saginata. Its larva is found in cattle and various other ruminants, but not in man. Its eggs, of which each segment may contain 35,000, are oval, larger than those of the tænia armata, and void of hooklets. The tænia saginata is found wherever raw or rare beef is used as food; consequently much more frequently in our country than the tænia armata. Leidy states that the tapeworms from Philadelphia and its vicinity which he had occasion to examine in the last twenty years, "perhaps in all about fifty," were specimens of tænia saginata. The condition assumes epidemic proportions in Abyssinia, where the flesh of cattle is eaten while still quivering with life. A mature worm was reared from a beef "measle," purposely swallowed by a student, in fifty-four days.

The tænia lata, or bothriocephalus latus, differs in marked degree from the preceding varieties. It is the longest of all the tapeworms, its 4000 segments attaining a length at times of twenty-five feet. The head is long and narrow, and is slit at the sides to form the bilateral elliptical suckers which give the worm its name. The segments not sharply separated are twice to four times as broad as long. The central uterus has the appearance of coils of intestine. The genital pore is central on the ventral face. The cysticercus is provided with spiculæ and a ciliated envelope, by means of which it swims in water. The eggs are oval and are furnished with a lid (operculum) at one end to afford escape of the embryo. This species of tapeworm is found wherever raw or partially cooked fish is used as food, consequently in Russia and Sweden, East Prussia, Poland, and parts of Switzerland, not in our country. The sole specimen thus far reported in our country was found by Leidy, derived from the body of a recently immigrated Swede. The mature tænia lata is found in the intestine of the dog as well as in man.

The tænia echinococcus, or hydatid tapeworm, is the smallest of all the tapeworms, measuring but one-quarter of an inch in length. It lives in the mature state in the dog and wolf, not in man; the whole duration of its life being not more than seven weeks. The head resembles that of a diminutive T. armata in that it is furnished with four suckers, a rostellum and a double row of hooklets. The segments, in number but four, progressively increase in size to the last, which is as large as all the rest, and which is alone mature.

The larva (echinococcus) of this tænia which infests man and many of the herbivora, horse, ox, sheep, etc., differs from that of all other tapeworms, in that it is endowed with the property of self-multiplication to a degree limited only by the restraint of outside pressure. The eggs issuing from the anus of the dog and brought often in contact with the nose and mouth of this animal, may be thence received into the mouth and stomach of man where the six-hooked embryo is liberated to penetrate the walls of the intestines and emigrate to various parts of the body. From the fact that the liver is found infested more frequently than all the other organs together, the inference is natural that the embryo is carried thither by the portal vein. Measly liver fed to dogs reproduces the mature T. echinococcus in the intestine of the dog. Having reached its destination in whatever organ, including the bones, the echinococcus develops the hydatid tumor, which may consist of a single cyst, or by proliferation from its inner wall of multiple daughter cysts, or from them in turn of granddaughter cysts, to the number of many hundreds. The fluid of hydatid cysts is clear and limpid. It is distinguished by the presence of common salt and the absence of albumen. The echinococcus tumor is rare in our country. Osler saw it three times in 800 autopsies in Montreal, and after ransacking museum catalogues, journals, society proceedings, etc., he could find but sixty-one cases in the whole of North America up to the year 1882. But it is safe to say that the majority of cases in our country do not find their way into print. For instance, the pathologist of the Cincinnati Hospital, a thoroughly competent observer, informed me, on the occasion of reporting the only case which occurred in my own practice, that he had himself seen three cases since the beginning of his service, none of which was reported. It is common in countries where the dog is a most intimate companion of man. In Iceland, where the dog shares with man both board and bed, the disease is epidemic, one-fifth of all sheep and one-seventh of mankind being thus affected, females, from their indoor life, oftener than males. Four to five per cent. of sheep are also thus diseased in Victoria, Australia, where the affection is likewise very common in man.

Mature tapeworms are seldom dangerous to man. In many cases they produce no symptoms of any kind, and their presence is recognized for the first time upon the post-mortem table. Or the discharge of segments with the stools, the appearance of them in the clothes at other times, is the first indication of their presence. Individuals who use water-closets may thus entertain these guests unawares until on some occasion the feces are voided visibly, as upon the ground in the open air or in a night vessel. As no mature worm penetrates the intestinal wall or evolves noxious products, what symptoms do occur are due to mechanical irritation of the intestinal walls or are reflex manifestations. Thus,

anorexia, nausea and vomiting, colic, diarrhœa or alternate constipation, heartburn, pyrosis, flatulence, the group of symptoms characteristic of gastric catarrh, summed up under the vague term dyspepsia, and, as effects, lassitude with malaise and depression of spirits are not infrequently present. A ravenous or insatiable appetite is exceptional, and when present is due not to the consumption by the parasite of nourishment, which is insignificant in amount, but to reflex irritation or defective assimilation, the result of irritation. More importance may be attached to morning vomiting which, in the absence of more common causes, pregnancy, gastric catarrh, cirrhosis, tuberculosis, Bright's disease, etc., may be an index to the condition. Young children or highly sensitive adults may exhibit more pronounced disturbance of the nervous system. Thus, dilatation of the pupils, itching of the nose and anus, palpitation of the heart, choreic manifestations, even veritable convulsions, epilepsy, have been observed in these cases. But the symptoms caused by intestinal parasites are exaggerated as a rule. All the symptoms mentioned may be produced by any cause that will excite the same irritation, and grave accidents are to be attributed to tapeworms only in cases where the symptoms subside with the expulsion of the worms. Rare cases of this kind are recorded. Thus, Williams describes the case of a young girl who was cured of a periodically recurring blindness and deafness of several hours' duration by the extirpation of a tapeworm, and Homolle reports a case of epilepsy cured in the same way. In some cases grave symptoms admit of a different explanation. In this regard, especial danger attaches to the pork tapeworm, in that the deglutition of its eggs or their premature discharge in the intestinal canal may lead to the development of cysticerci in the same host. This accident may take place in sleep when the hand is used to relieve itching or irritation at the anus or moist segments escaping from the anus and crawling about on the skin are grasped in relief of unpleasant sensations. Küchenmeister often found fingers contaminated in this way. Cases of self-infection have also happened from careless handling of worms after their expulsion. Moreover, the act of vomiting may introduce segments into the stomach, where eggs may be liberated to develop into cysticerci. Seeger mentions six cases of ejection of tapeworms by the act of vomiting, and Rebsamen reported the case of a woman who withdrew a tænia lata from her mouth with her fingers. Frankenhäuser relates a case of cysticercus in a patient who had previously vomited a tapeworm, and Lewin (Charité Annalen V.) collected a number of such cases. In two of Gräfe's cases of cysticercus of the eye, the patients, while hosts of the worm, had suffered from the vomiting of pregnancy; and in the cases of cysticercus of the brain reported by Möller, the patient had had a tapeworm expelled twenty years before death. Thus, the existence of severe nervous symptoms would awaken the suspicion of the presence of cysticerci. But examples of this kind are quite exceptional. In the vast majority of cases grave nervous symptoms are due to other and more obvious causes.

The diagnosis of the condition of the patient is sometimes quite obscure. The only positive proof of the existence of tapeworms in the body is the presence of segments in the stools or clothes. As in most cases eggs are not discharged in the intestines, it is very rare to find them in the stools. Where reasonable doubt exists, the administration of a cathartic or of an innocent anthelmintic, to be followed by a cathartic, may secure the proofs. Differentiation of the form of tapeworm is easily made. The segments are flattened by pressure upon the object-glass and examined with a power of 500 diameters, when the characteristic features of each form become apparent at a glance. Dried specimens should be first softened in water. The occasional evacuation of segments, independent of stools, or the discovery of them in the clothes, speaks in favor of the tænia saginata. The echinococcus tumor may sometimes be recognized by its situation. It has, as stated, a marked predilection for the liver. Or the fluid contents of a cyst may be withdrawn by an aspirator and tested for the presence of salt and the absence of albumen. Scolices and hooklets may be exceptionally discovered in the fluid on microscopic examination.

Palpable tumors communicate to the hand a peculiar unmistakable tremulous thrill. Deep-seated fluctuation of a hydatid tumor may be distinguished from that of an aneurism, abscess, or common cyst by the examination of aspirated contents. In all cases of tapeworm, and especially after treatment, the feces are to be subjected to close examinations by repeated washings that the minute and easily overlooked head of the worm may be discovered.

Prophylaxis. The subjection of meat to a boiling temperature throughout, which effectually destroys all cysticerci, is the chief preventive of tapeworm. The recognition of this fact with regard to the trichnia spiralis has already diminished the number of cases of tænia armata. Cleanliness is the factor of next importance. The oriental custom of ablutions before each meal may be commended in this regard. Individuals affected with the disease should be enlightened as to the fact that they are possible sources of infection of others. Bettelheim speaks of having seen in a house of poverty and squalor segments of tapeworm deposited upon and crawling about the floor, furniture, and beds. Butchers, cooks, all persons employed in the preparation and distribution of meats, should be cautioned as to the necessity of cleanliness of hands, instruments, vessels, and clothing. To prevent infection of animals with eggs, habits of decency in regard to the deposit of feces should be enforced, and check should be put upon the barbarous custom of promiscuous defecation. A Texas physician informed Prof. Leidy, to whom he had sent a piece of measly pork for examination, that all the pigs in the place were thus affected and that there was not a privy in the whole village. In the administration of anthelmintics to the subjects of the pork tapeworm, selection should be made of such remedies as will not cause vomiting. Especial attention is to be paid in this regard to the relief of the vomiting of pregnancy. Physicians as well as patients need repeated injunction against the careless handling of tapeworms in their examinations. Specialists who have devoted a large part of their lives to the study of intestinal parasites become exceedingly careful in their manipulations. Küchenmeister states that he always handles tapeworms with two pairs of long forceps seizing them as near the points as will secure firm purchase; and Cobbold warns against the danger of leaving specimens about or care-

lessly throwing them away, with the emphatic injunction to destroy them by fire.

The Greek and Roman physicians possessed sixty remedies for the cure of tapeworm, and the number has been greatly increased in our day. But few of these agents, however, have stood the test of time. Such uncertainty has attended the use of most of them as to have left the treatment of the condition a fertile field for quacks. This uncertainty depends, however, upon the lack of observance of a few simple precautions, the chief of which consists in the evacuation of other contents of the bowels as effectually as may be, that the remedies used may come in direct contact with the worm. Elaborate preparatory and supplementary treatment is now in the main superfluous, but a light diet during the day, or better, a fast broken only by a cup of coffee or a glass of milk should precede the administration of the remedy selected. These remedies may be ranked in efficacy as follows:

1. The bark of the pomegranate root of which three ounces should be macerated in twelve ounces of water for twelve to twenty-four hours, to be then reduced one-half under gentle heat. The whole quantity is to be taken in divided doses in the course of an hour. Pomegranate root remains the most effective of all anthelmintics, and would long since have excluded all others did it not at times produce nausea, vomiting, and colicky pains. To avoid the first of these evils, Bettelheim suggests the introduction of the infusion into the stomach by means of the stomach pump, and to obviate all of them, Feraud recommends pelletierin, an active alkaloid of the root named in honor of the discoverer of quinine. One to two drachms of the infusion of senna is to be taken on the morning following a day of fasting, and in the course of an hour one-fourth to one-half of a grain of the tannate of pelletierin suspended in water. Half an hour later the same dose is repeated, to be followed in an additional half hour with a tablespoonful of castor oil, the patient remaining meanwhile quiet in bed, to avoid disturbance of the stomach. In one instance twelve beef tapeworms were expelled at once in this way.

2. Turpentine is a powerful tæniacide, but the use of it is liable to cause headache, pain in the stomach, fever, and strangury. These effects are, however, much less frequent after large than small doses. Hence the dose for an adult should be never less than one to two ounces, for a child, one drachm to one ounce according to age. It may be administered in emulsion with white of egg or be briskly stirred in half a glass of milk and swallowed rapidly. Should it fail to act as a cathartic, it should be followed with a dose of castor oil.

3. Male fern, the ethereal extract, two drachms in four or five gelatine capsules of which one may be swallowed every five minutes with the aid of a cup of coffee. A dose of castor oil with brandy should follow the capsules in the course of half an hour.

4. Kousso, koussin, pumpkin seeds, santonin, kamala, carbolic acid, zinc, and other parasiticides of less value.

Every attempt at treatment being a forcible intervention, only such individuals should be subjected to it as are known to be affected. The mere statement of a patient is not sufficient proof, and cases of tæniaphobia do not justify it, on so-called psychological grounds, because failures only aggravate the condition as a rule. Pregnancy, advanced age, debility from any cause are contraindications to all treatment. The physician must be awake to cases of deception. Heller reports the case of a child finally debilitated by repeated treatment because of the continued exhibition of segments of the worm, when, upon closer examination, it was discovered that the fragments did not come from the child at all, but from a lazy nurse who made a convenience of the child's stool chair.

Echinococcus cysts are not amenable to relief by internal medication. If further evidence than the failure of every kind of drug were necessary to prove this fact it may be found in the statement of Leidy, who discovered in the body of an English sailor, sent to him for dissection, the tissues having been thoroughly bleached by an injection of zinc chloride several days after death, a hydatid tumor of the size of the fist in the right iliac region full of daughter cysts, containing still living scolices. The most approved method of treatment of hytatid tumors is by aspiration of their contents. Murchison reported, of forty-six cases thus treated, thirty-five successful results. In ten cases subsequent suppuration necessitated incision, whereby eight cases recovered, and two died. The remaining case died of acute peritonitis in twenty-four hours. Fogg, Hilton, Durham, and Handfield report nine cases cured by electrolysis. Jonasen, of Iceland, still adheres to opening by the caustic method of Récamier. The rare form of degeneration known as the multilocular cyst is always fatal.

ORIGINAL ARTICLES.

SUBCUTANEOUS DIVISION OF URETHRAL STRICTURE.[1]

By C. H. MASTIN, M.D.,
of Mobile, Alabama.

(Concluded from page 287.)

The healing and suppuration of an open wound being long and tedious, and consequently exposing a patient to the risks of pyæmia, whilst structures having no connection with the existence of the stricture are unnecessarily divided, naturally induced the profession to seek other and less formidable measures of relief. These facts led Mr. Henry Dick, of London, in the year 1853, to publish, in the *Medical Times and Gazette*, a critique upon the operation of Mr. Syme, and at the same time to lay before the profession a description of a new operation, which he termed "The Subcutaneous Division of Stricture." Subsequently he presented, in 1855, a memoir to the Academy of Medicine of France upon the same subject, and therein gave the histories of several successful operations which he had performed. After this the operation was then adopted by Mr. William Allingham, and also by Mr. William Adams, both of whom made favorable reports of successful operations.

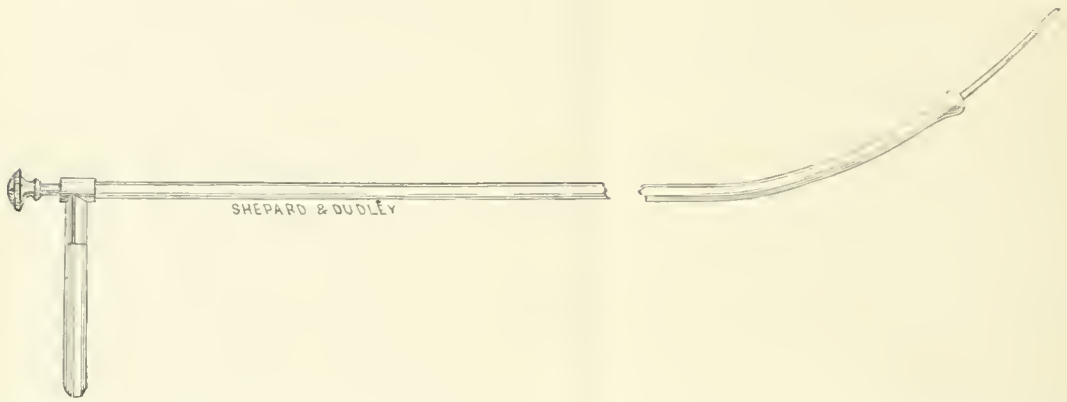
I will now briefly describe the method of Mr. Dick, and then close this paper with an illustration of an operation which I devised in 1868, and which,

[1] Read before the American Surgical Association, May, 1886.

to the present time, I have seen no valid cause to discard.

His method consists in first dilating the stricture sufficiently to admit the director of his catheter, which is a medium-sized catheter of moderate curve, upon the end of which are two buttons or knobs having a groove between them, which groove is continued on, into, and along the director; the catheter contains the small grooved director which can be drawn in or pushed out, so as to traverse the stricture (Fig. 8).

Fig. 8.



The operation is done in the following manner: The catheter, with the director concealed within it, is passed down the urethra until its point reaches the anterior face of the stricture, when, by a gentle manipulation, the point of the director is made to engage the stricture, and is then passed on until it enters the bladder; the surgeon then takes a very small sharp-pointed tenotome (Fig. 9), and, feeling in the perineum with the index finger of his left hand for the buttons or knobs, plunges the knife between them into the groove and along the director through the stricture, being at the same time careful to see, or rather to feel, that the stricture is freely cut throughout its entire length, the edge of the tenotome being directed downward. After the stricture has been freely incised, the director is withdrawn into the catheter, which is now removed from the urethra, and a full-sized catheter passed into the bladder to ascertain whether the urethra has been fully cleared, and also to empty the bladder of any urine which may be present. The little wound is covered by a bit of adhesive plaster, a compress with a T-bandage completes the dressing. No retained catheter is left in the urethra, but whenever there are calls to urinate, the water is drawn off with either a silver or soft catheter. This is certainly a very unique and ingenious operation, and one which strikes at the chief point of objection to all external operations done in the old way, viz., an open wound in the perineum which, in most cases, must heal by the slow process of granulation. Still there are objections to Mr. Dick's operation which will necessarily prevent its coming into general use. In the first place, it is difficult to perform, and requires a degree of dexterity which does not belong to the profession at large; then we have no absolute proof that the director has traversed the stricture, for it may have penetrated a false route, and the incision made subcutaneously, in that event, might be productive of serious consequences. Then, again, he holds as a necessity that *the stricture must, to a small extent, first be dilated*: this is required before his conductor can be introduced. Now, if it is possible to dilate the stricture sufficiently large to admit his director, I hold, upon the same grounds of objection to the operation of Mr. Syme, that there is no necessity for an external operation, for the reason that, if a director can be passed, it is possible to dilate, or, this failing, then to do the safer operation of internal urethrotomy.

Fig. 9.

Mr. W. F. Teevan, of London, has proposed and executed a modification of the operation of Mr. Dick, having the same end in view, viz., to do away with a large external incision, and substitute in its place a small opening through which he practised a subcutaneous urethrotomy. The method employed was simply one in which a small whalebone guide was worked through the stricture, and over this a small conducting catheter was in its turn introduced into the bladder; then along its groove the tenotome of Mr. Dick carried through the contraction, and the after-treatment conducted as in the operation of Mr. Dick. I am not informed of the success which has attended this procedure of Mr. Teevan; but if permitted to judge of the operation from the instruments which he used (Fig. 10), I am not very favorably impressed with it.

I now desire to describe briefly an operation which I have employed since the year 1868, whenever an occasion has demanded an external section. Thus far it has proved entirely satisfactory to me, and especially so to those upon whom I have had an occasion to perform it.

In the year 1872 I wrote a paper upon the result of my operations by this method, and since that date to the present, with an increased experience, I have seen no reasons to alter the views which were then expressed. I now claim nothing of originality for the operation, since it is based almost entirely upon the old *le boutonnière:* the incision being very small, and made anterior to the stricture; then, a very small probe-pointed director, or whalebone guide is passed along through the stricture, and a delicate tenotome incises its upper wall subcutaneously; the small wound in the integuments is closed by pin sutures, and left to heal by primary union. Adhering to the maxim, "dilate where you can, cut where you cannot," I only resort to this operation in those cases where no catheter or guide can be made to traverse the urethra from the meatus to the bladder; cases which require some operation for the immediate evacuation of retained urine, and in which it is not possible for me to perform an internal urethrotomy.

The patient, duly prepared by opening the bowels freely with an enema, and a hot hip bath to tranquillize the nervous system, is placed upon a table, then secured in the ordinary position for cystotomy, and anæsthetized. I now pass down the urethra the tube of Benique (Fig. 11), which is a plain silver tube open at both ends, about nine millimetres in diameter, and from six to eight inches in length; this tube protects the walls of the urethra, and puts on the stretch the face of the stricture. The tube is now filled with a bundle of small filiform whalebone probes which are carefully passed down to the stricture; by trying first one and then another it is possible that one may engage the opening and pass on into the stricture. This being accomplished, I remove the disengaged probes together with the tube, and after securing the probe in the bladder, I pass over it a Wheelhouse staff which has been drilled through its end to answer the purpose of a Gouley staff, and carry it down to the stricture; it is now handed to the assistant, who holds it lightly, yet firmly, against the coarctation, whilst I open the urethra in the groove of the staff, making an incision about half an inch in length. I then draw outward the staff just sufficiently to enable me to find the whalebone probe as it passes through its end and on into the stricture; this I secure by passing a small blunt hook behind it, after which the staff is removed entirely from the urethra, and the distal end of the probe drawn out through the little wound which has been made; and now, over the probe I pass a little gorgeret (Fig. 12); this has its blade directed upward, and being run along the probe, as its guide, it passes through the opening into the

FIG. 10.

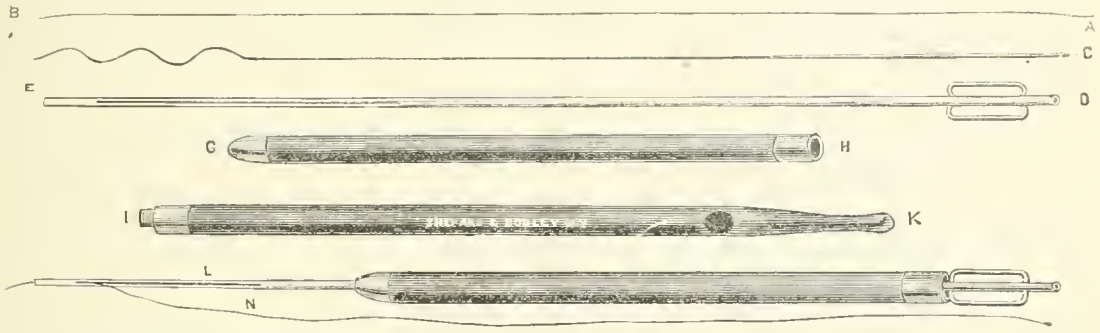


FIG. 11.

FIG. 12.

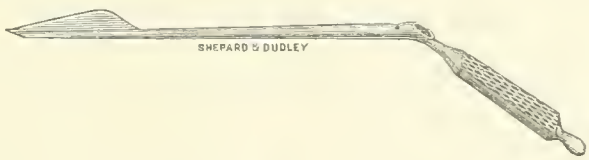

FIG. 13.

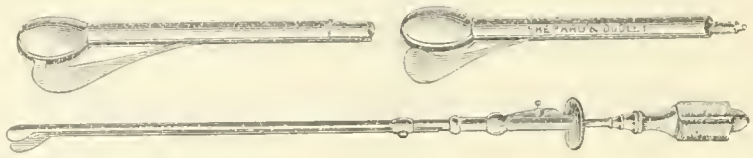
urethra, and then down the stricture, which is cut on its superior face. A catheter is now passed along the entire urethra into the bladder and the urine evacuated, after which I carefully examine the site of the stricture with graduated metallic ball probes (Fig. 13) for the purpose of detecting any bands which, perchance, may remain: if found, they are divided by the retrograde urethrotome of Civiale (Fig. 14), and the full calibre of the urethra restored.

thread in the form of the figure 8; then the sound is removed, and its place occupied by a full-sized catheter passed down to the prostatic urethra, but not into the bladder. The patient is put in bed and kept on his side, with instructions to push the catheter into the bladder when he has a call to urinate, and always, so soon as the urine has been discharged, to withdraw the catheter sufficiently far to get it out of the bladder, but not beyond the

Fig. 14.



In the event, however, that it is not found possible to pass a whalebone probe in the first instance, so as to gain command of the stricture before opening the urethra, I then pass either the staff of Wheelhouse, Gouley, or an ordinary staff of slight curve with deep groove, down to the face of the stricture and practise the Leeds operation, with the exception that I do not rip open the whole stricture, but having gotten the whalebone probe through the coarctation, I thread over it the little gorgeret and incise it on its superior face, just as described in the instance where the probe was passed along the tube of Benique, always taking care to sever any and all bands which may remain. This opening simply serves the purpose of shortening the canal and bringing us nearer the obstruction; it furnishes us a passage of only some few lines in length in which to manipulate our instruments, in place of a canal of several inches in extent, as would be the case if the urethra had not been opened. I thus, virtually, perform an internal section; I do not rip open the whole coarctated canal and lay bare to the external wound the cavity of the urethra, but I leave it, so far as the stricture is in question, just in the same condition as an urethra upon which I had done an internal urethrotomy.

In the absence of the little gorgeret, I have found a very narrow-bladed urethrotome of Maissonneuve, conducted by a small filiform bougie passed through the external opening and coiled within the bladder, to serve a most excellent purpose, provided the staff is grooved on its concavity, so as to insure the incision being made upon the roof of the urethra. Such, in brief, is the method I have adopted of operating *externally*, and find that it is easy of execution, and satisfactory in its results.

Having carefully divided any existing bands, and restored the lumen of the urethra, I then pass a sound into the urethra, and, after the slight oozing of blood has ceased, I wash the parts thoroughly with cold water, to which may be added either a chlorine or weak mercury solution for the purpose of cleansing and disinfecting the wound; now I close the wound accurately with two or three pin sutures, passed deep enough to engage the divided edges of the urethral canal, and, after coaptating the edges of the skin, I encircle the pins with a flat stricture. This catheter is used for only twenty-four to thirty-six hours, just long enough to insure the protection of the wound from the passage of the urine until it has been in a measure glazed over, and the strictured portion softened up by the presence of the inlying catheter. On general principles I am opposed to the *sonde à demeure* or retained catheter, and for obvious reasons too patent to need mentioning here; but the sound or catheter, used as I suggest, answers all the purposes for which it is intended, and keeps the urine from the wound until it is sufficiently protected by a glaze which prevents the urine passing into the external incision. At the expiration of this time the catheter is dispensed with and the patient left to pass his urine at will. About the fourth or, at latest, the sixth day, I remove the pins, and do nothing more to the wound save keep up the dressing of lead-water and opium—which is applied immediately after the operation—for two or three days longer. Now the patient is permitted to get up and stir about, and within eight to ten days he resumes his former vocations. The after-attention is such as is usual in all operations for stricture, whether they be external or internal, viz., the systematic use of gradually increasing steel sounds until the maximum calibre attainable in the special urethra has been reached.

With this course judiciously pursued, I find that I am able to discharge my patients perfectly healed within from eight to twelve days; and in not a single instance, out of some twenty-five to thirty operations, have I had any hemorrhage or the annoying complication of urinary fistulæ to contend with.

The advantages to be derived from this operation are, the short time of confinement for the patient, freedom from hemorrhage, quick union by primary adhesion, and the small amount of resultant cicatricial tissue, which is always deposited in greater proportion the longer the healing process continues. The retained catheter for the first day or two does good rather than harm, since it protects the fresh incision from the toxic effects of the urine until it has become glazed over with lymph, and acts, at the onset, by pressure upon the divided stricture, compressing the vessels which have been divided and which might bleed after reaction; it also sustains the

urethra as a splint, and prevents the stricture from reuniting until we have time to begin gradual and systematic dilatation with the steel sound. The comparative immunity from urethral fever which my patients have enjoyed after this operation, I feel certain, is due almost entirely to the use of the inlying catheter as I employ it. I do not desire to be understood that I advocate the use of a retained catheter throughout the entire confinement of the patient to bed, but that I use it only for the first twenty-four to thirty-six hours—just sufficiently long to permit the wound to glaze over with lymph, and model, as it were, the granulations by gentle pressure.

In examining the details of the last ten operations which I have done by this method—all of them bad cases—I find that they were enabled to get out and be around the city in the following order: 3 on the fourth day after the operation, 1 on the fifth day, 2 on the sixth, 2 on the seventh, 1 on the ninth, and 1 on the twelfth. The others recovered in about the same proportions.

I am not apprised if any other method of performing external urethrotomy has afforded like rapid results.

ADDITIONAL CASES OF THE SÄNGER CÆSAREAN OPERATION.

Reported by ROBERT P. HARRIS, A.M., M.D.,
OF PHILADELPHIA.

IN THE MEDICAL NEWS of July 17th, I presented a tabular record of 28 Sänger operations, of which 23 were performed in Continental Europe, and 21 of these in Germany. Mainly through the kindness of Dr. Sänger and other correspondents, I have received, in two months, an addition of 10 cases, making 38 in all, of which 33 are European, and 14 belong to the current year. Of these 14, 12 were saved, and probably all of the children, but certainly 13, the fate of 1 not having been mentioned.

The 33 European operations saved 26 women and 31 children, a record much more promising than that by the Porro method. It must be very gratifying to my friend Dr. Sänger to feel that he has been the originator of this life-saving improvement, and to find such noted gynecologists as Profs. Breisky, of Prague, Chiara, of Florence, and Ottavio Morisani, of Naples, making trial of it.

In my former record the cases of Drs. Prochownick, of Hamburg, June 27, 1884, Veit, of Bonn, June 25, 1885, and December 21, 1885, Schauta, of Innsbruck (his second), Dec. 28, 1885, and Prof. Breisky, of Prague, were omitted from their respective places. Dr. Prochownick's patient was a primipara of thirty-eight, having a deformed pelvis, with a conjugata vera of 3⅛ inches, and was in labor forty-four hours; he saved both mother and child. Dr. Schauta's patient was a primipara of twenty-five, and in labor twenty-eight hours; she and her child were likewise saved. Prof. Breisky operated, Feb. 4, 1886, upon a 3-para of twenty-eight, who had been in labor three days. The cause of obstruction was a cystic tumor strongly attached to its surroundings, and in the Douglas cul-de-sac. Septic infection was produced by the cyst contents, and the woman died the next day; the child was saved.

Dr. Leopold operated for the tenth time, in June, 1886, the patient having pelvic contraction, and saved both mother and child. This gives him a loss of one woman in ten, or, for his hospital, a saving of 10 women and 11 children from 11 operations.

Prof. Domenico Chiara, of Florence, operated on June 29, 1886, upon a primipara of twenty-one, having a rachitic pelvis, conjugata vera 2¾ inches. The woman was sufficiently recovered to leave her bed for a few minutes on the tenth day; the fœtus was saved.

Prof. Morisani operated upon July 2, 1886, and thought his the first Sänger case in Italy, but was three days too late. He unfortunately lost his patient in thirty hours, from what cause his letter does not state, neither does he mention the fate of the child. An autopsy showed that both the serous and muscular edges of the uterine wound had united. He expressed himself as very much pleased with the prospective value of the improvement, in its application to Cæsarean cases, as a means of lessening their danger.

Dr. Paul Bar, of Paris, operated last month (July), in a case of sarcoma of the pelvis, and saved both mother and child. This was the second operation in France. The record now stands as follows:

Countries.	No. of cases.	Women saved.	Women lost.	Child'n saved.	Child'n lost.	Percentage of women saved.
Germany	25	21	4	24	1	84
United States	5	0	5	2	3	0
Austria	4	2	2	4	0	50
Italy	2	1	1	1	?	50
France	2	2	0	2	0	100
Total	38	26	13	33	4	

Percentage of women saved in all countries, $68\frac{5}{19}$
Percentage of women saved in Europe alone, 78

It will be seen that our position is not at all creditable to us as a nation. Standing second in point of numbers, we are least in respect to success, both in the proportion of women, and of children saved. Under an improved system of operating, we are retrograding instead of advancing, and are being left far behind by the Cæsarean operators of countries which, up to twenty-five years ago, had a much higher rate of mortality than existed in the United States. As I have often contended, there is a decided connection between the prior death or destruction of the fœtus and the subsequent loss of the mother; and here we find there has been no exception. To do better in the future, we must bear in mind the importance of making the operation one of choice, and not one of compulsion, after every other expedient has been tried. In a case of pelvic obstruction, first carefully determine the working space; do this early in the labor, and then operate, if the space measures so small that in all probability the Cæsarean section will at the last be a necessity of delivery.

September 11, 1886.

ON THE CAUSES OF DYSPNŒA AND CARDIAC FAILURE IN HIGH ALTITUDES.

By FRANK DONALDSON, Jr., B.A., M.D.,

late scholar in biology, johns hopkins university, and chief of clinic for throat and chest, university of maryland.

In the course of some experiments during the past winter, upon the physiological effects of rarefied and compressed air, and reported to the American Climatological Association in May,[1] I was often struck with the fact that sudden and considerable rarefaction of the air produced not only extreme dyspnœa but also a rapid, irregular, and intermittent pulse in the animals experimented upon.

The apparatus used by Prof. Martin and myself was the pneumatic cabinet, at present so much employed for the application of rarefied and compressed air to respiratory diseases, and which is used somewhat indiscriminately, without proper regard to the possible dan. er of subjecting patients with cardiac disease to treatment by this method. The animals, be it said, were placed in the cabinet in the same manner and subjected to the same changes of pressure as are patients.

In our experiments it was found that:

I. When the animal is breathing air from outside the cabinet, rarefaction of air within the cabinet *causes a marked fall of general arterial pressure*, but has no influence on the pulse-rate.

II. This fall of systemic arterial pressure depends on two factors: greater flow of blood to the skin when the air around the animal is rarefied, and greater accumulation of blood in the lungs when they are distended.

III. Of these two factors, accumulation of blood in the lungs is the more effective; for, if the animal breathes air from the cabinet and not from outside, rarefaction of air within the cabinet (in this case accompanied by no special expansion of the thorax) has but a trivial effect in lowering arterial pressure, unless the rarefaction is very considerable—about what would correspond to three or four thousand feet—when the fall of pressure was more marked.

IV. When the animal is breathing external air, rarefaction of air within the cabinet usually has no effect upon the respiratory rate or the extent of individual respiratory acts, unless the fall of blood-pressure is considerable. *If it is considerable, symptoms of anæmia of the medulla oblongata are seen. In most cases there is more forcible dyspnœic breathing; in some there are dyspnœic convulsions similar to those which occur when an animal is bled to death*, and due to the same cause, viz., deficient blood-flow to the respiratory centre.

So convinced was the writer from these facts, of the danger of this method of treatment that he was led to lay down the following rule, and upon which special stress was laid, viz., before deciding a person to be a proper subject for treatment by pneumatic differentiation, *thorough examination* should be made of the *heart; and that no person found to have insufficiency or stenosis of the mitral or aortic valve, or the slightest tricuspid regurgitation, or a fatty or weak heart, should, under any condition, be subjected to treatment by rarefied and compressed air.*

I was not aware that this point had been emphasized before as to the danger in heart disease of the rarefied and compressed air treatment by this method, and was therefore much interested in Dr. Loomis's paper read before the same Society and just preceding my own. In this article, entitled "The effects of high altitudes on cardiac disease,"[1] Dr. Loomis gives the history of six cases of cardiac failure directly due to removal to high altitudes. He has records, however, of twenty-two. The extreme importance and novelty of these cases entirely justify the insertion here of two.

Case I.—"In the summer of 1880, during my vacation at St. Regis Lake, in the Adirondack Mountains, I was requested to visit a gentleman who had just arrived from New York and was thought to be dying. I found a gentleman, forty years of age, sitting at an open window, gasping for breath, and deeply cyanosed. No distinct radial pulse could be detected, his extremities were cold, and his body was covered with a profuse perspiration; he was semi-conscious, unable to speak or swallow, and seemed to be dying. Neither heart-sound could be distinctly heard. After the hypodermatic administration of ten minims each of tinct. digitalis and Magendie's solution of morphia, with the free use of hypodermatics of brandy, he rapidly recovered from his extreme condition, and in a few hours was comparatively comfortable, but unable to lie down, and was only partially relieved of his dyspnœa, the radial pulse continuing rapid, feeble, irregular, and intermitting. The next morning I obtained the following history:

"Three days before, Mr. C. had left New York City, feeling well, although for two or three months before he had noticed that he became easily fatigued, had dyspeptic symptoms, lost flesh, and spent restless nights. When he reached Plattsburg the evening before (the altitude of which is 150 feet above sea-level) he felt better than when he left New York, slept unusually well during the night, and started at eight in the morning for St. Regis Lake. When he reached an altitude of about 1000 feet his breathing became difficult, and, as he reached higher altitudes, the difficulty increased, and was accompanied by cardiac palpitation and a sense of oppression in the epigastrium. The dyspnœa and oppression became so urgent before he reached St. Regis (the altitude of which is about 2000 feet) that his friends had to support him, and, when taken from the carriage on his arrival, he was thought to be dying. A careful physical examination twenty-four hours after showed a diffused, indistinct cardiac impulse; the area of præcordial dulness was greatly increased both to the right and left. The first sound of the heart could not be made out; its time was occupied by a loud systolic murmur. The pulse was rapid, feeble, irregular in force, and at times intermittent; fine râles were heard at the base of both lungs. One examination of his urine gave negative results. After treating him for three days, with little apparent improvement in his cardiac symptoms, I advised that he should be taken to a lower altitude.

"When he reached Plattsburg on his return his dyspnœa was markedly relieved; when he reached his country home on the Hudson he had so far improved that he was able to walk on a level, and to lie down with his head and shoulders slightly elevated, although

[1] Preliminary Account of Experiments in regard to the Circulatory and Respiratory Changes observed in Animals placed in the Pneumatic Cabinet, by H. N. Martin and Frank Donaldson, Jr., New York Medical Journal, May 15, 1886.

[1] New York Med. Journal, June 12, 1886.

his dyspnœa, epigastric oppression, and irregular heart-action continued; his feet soon became œdematous, and six weeks later he died with general anasarca and heart insufficiency. No post-mortem examination was made. His family physician told me, some time after, *that he had never detected signs of cardiac disease until his return from the mountains, although he carefully examined his heart two weeks before he started on his summer trip.*"

CASE II.—"Mr. M., aged fifty-two, with recognized aortic insufficiency, which had never given him serious trouble (*in fact, he was not aware that he had cardiac disease*), on the 10th of August, 1882, started with his family on a pleasure trip through the Adirondacks. When he reached an altitude of about 1000 feet he began to suffer with dyspnœa and cardiac palpitation; when he reached St. Regis Lake he was markedly cyanosed, his respiration was gasping in character, and his pulse could not be counted. His apex impulse was diffused and indistinct, and he was having quite profuse pulmonary hemorrhage. I ordered a calomel purge, and ten drops of tinct. digitalis every three hours, which was followed by marked relief within twenty-four hours, although his dyspnœa and cardiac symptoms were not sufficiently relieved to allow him to lie down. A physical examination showed extensive cardiac enlargement, a diffused and indistinct apex beat, a feeble and irregular heart-action, an absence of the muscular element of the first sound, but no murmur could be detected. The urine contained albumen, but no casts; crepitating râles were heard over the base of both lungs. I advised that he return immediately to his home in Brooklyn, which he reached, the third day after, very much improved. His dyspnœa was so much relieved that he was able to lie down; his feet and legs soon became œdematous, general anasarca followed, and in two months he died suddenly. No autopsy was made, and I could get no intelligent account of the immediate cause of his death."

Dr. Loomis then goes on to say,

"In these cases which I have quoted, as well as similar ones which have come under my observation, *the ventricular dilatation*, which was unquestionably the cause of the sudden development of the distressing symptoms, and from which dated the commencement of the fatal issue, seemed to be directly due to the effects, on the *cardiac circulation, of the change from a low to a high altitude.* I do not maintain that sudden cardiac dilatation might not have developed in any one of these cases under other conditions, but I do maintain that change in atmospheric pressure is a very important cause of sudden ventricular dilatation when any degree of heart insufficiency preëxists."

Finally, he declares that only with danger can a person whose heart is weak, fatty, or diseased, pass rapidly from a low to a high altitude, and, indeed, I gathered from his subsequent remarks that a person with cardiac disease should under no circumstances be sent to high altitudes.

Dr. Loomis then, had arrived at the same conclusion from clinical experience as the author had experimentally, and it seems that we may rest assured that there is great danger for the diseased heart either in high altitudes or in any form of treatment by rarefied and compressed air. This fact being established, our purpose is to inquire into the cause of dyspnœa and cardiac failure under these conditions.

To do this it will be necessary, first, to give the latest accepted explanation of the circulatory changes which take place in ordinary quiet respiration of air at normal pressure—750 millimetres of mercury—and then to see how high altitudes may affect these normal respiratory and circulatory phenomena.

It is very generally stated that the cause of dyspnœa and shortness of breath in high altitudes is the want of oxygen; that the system needing oxygen, more blood has to be sent through the lungs in a given time, thus increasing the amount of work to be done by the heart, which often dilates under the sudden strain. Such explanation, though applicable for very high altitudes, is at the same time based on a misconception.

1st. The partial pressure of oxygen at normal atmospheric pressure is equal to 152 millimetres of mercury.

2d. So long as the partial pressure of this gas remains above 25 millimetres of mercury (one inch) the amount taken up by the blood will depend upon the amount of hæmoglobin in that liquid, and not on how much oxygen there is in the air.[1]

3d. The partial pressure of oxygen even at so great a height as 10,000 feet would be 101 millimetres of mercury, at which the hæmoglobin could get all the oxygen necessary.

But it may be urged, Paul Bert found an increased amount of hæmoglobin in the blood of animals in high altitudes, which would show a necessity on the part of nature for more oxygen. True, but this change takes place only after a very long time, probably not in one generation. Again, it may be objected that in many of those very cases sent to high altitudes the blood is poor in hæmoglobin. Doubtless this is true, but it is not the sick only, by any means, who suffer from dyspnœa and cardiac failure in high altitudes.

It is not necessary in this article to go into the various theories of the aspiration of the thorax, advanced by Poiseuille, Quincke and Pfeiffer, Funke and Latschenberger, Bowditch and Garland, Mosso, Hegel and Spehl, and others. I shall refer only to the work of de Jager, whose explanation of the respiratory phenomena has, on the whole, the greatest experimental proof to support it.[2]

As to the influence of the normal respiratory movement upon the circulation. In any given inspiration the chest cavity is enlarged, negative pressure is created in the thorax; not only the lungs, but the right side of the heart and the intrathoracic portions of the systemic veins, are expanded in consequence, and the blood is drawn toward the great veins and right side of the heart. Such being the general effect of negative intrathoracic pressure, what is its effect upon the blood-flow through the lungs, upon the intrathoracic vessels, and finally upon the systemic circulation?

De Jager holds that though the negative pressure is exerted equally on the pulmonary artery and vein, the effect upon the blood in each is very different,

[1] Martin, Human Body, p. 384, 1st edition.

[2] For the *résumé* of the work of de Jager, with a critical examination of his theory, I am greatly indebted to my friend, Dr. W. H. Howell, of Johns Hopkins University, who kindly allowed me to make use of his lectures on the aspiration of the thorax.

for the walls of the pulmonary artery are much thicker than those of the pulmonary vein, and any want of pressure would be transmitted through them upon the blood much less readily. Again, the walls of the pulmonary artery are normally distended by a pressure of from 30–40 millimetres of mercury, and so the slight increase of negative pressure occurring during inspiration would probably have little or no effect in distending the pulmonary artery. On the other hand, the blood in the pulmonary vein is under little, if any, positive pressure, and so diminution of pressure would distend its walls considerably. De Jager, therefore, holds that we would have the normal conditions during life more nearly represented if, in an artificial thorax, the pulmonary vein should be exposed to the same negative pressure as that expanding the lungs, while the pulmonary artery was left under a constant pressure of one atmosphere, for instance.

Experimenting in this way, he found that the stream velocity (the amount flowing from the pulmonary vein in fifteen seconds) is markedly greater during *expansion* than during *collapse;* the effect then of normal inspiration, on the whole, is to increase the quantity of blood flowing through the lungs, probably by increasing their capacity, and thus diminishing the resistance to the flow. De Jager, in his second paper, gives the final opinion that "the respiratory waves in the blood pressure in the dog in normal quiet respiration are caused by changes in lung circulation. The first sinking of pressure at the beginning of inspiration is a capacity curve—*i.e.*, due to increased capacity of the lung vessels; the following rise, a stream velocity curve"—*i.e.*, caused by an increased flow through the lungs. In a like way, the rise at the beginning of expiration is a capacity curve—*i.e.*, owing to a diminished capacity; the succeeding fall, a stream velocity curve, due to diminished flow through the lungs.

The influence of respiration upon the heart and great vessels. The first effect of the negative pressure of inspiration is a diminution of pressure on the heart and intrathoracic vessels, and a consequent *sucking* of blood into the right side of the heart, which in turn is sent through the increased area of the lung vessels to the left heart, and thence to the systemic circulation, causing a rise of pressure. Another important element in the respiratory waves of blood pressure is the change which takes place in intra-abdominal pressure in inspiration. Luciani and Schweinberg maintain that the descent of the diaphragm causes increased abdominal pressure, which assists the rise in arterial pressure, 1st, by driving the blood out of the abdominal veins toward the heart; 2d, by compressing the abdominal arteries (a questionable supposition). Another cause of increased pressure during inspiration is the increase of heart rhythm, due, according to Fredericque (*Archives de Biologie*, 1882), to a rhythmic automatic discharge from the cardio-inhibitory centre—the discharge depending in some way on the rhythmic discharge from the neighboring respiratory centre.

The effects, then, of the negative pressure following inspiration, are an increased blood-flow to the large intrathoracic veins, and to the right heart; an increased heart capacity, especially of the right side; an increase in intra-abdominal pressure, forcing onward the blood; an increase of capacity in the pulmonary veins; an increased blood-flow through the lungs and to the left heart; an acceleration of the heart rhythm, and, finally, increase of systemic arterial pressure.

Such, in brief, is the theory of the circulatory changes which take place in ordinary respiration. It remains for us to inquire how the cycle may be affected in high altitudes.

However much the phenomena of normal quiet respiration may be changed in a highly rarefied atmosphere, the chief and immediate cause of dyspnœa and cardiac failure, may, I think, be traced to *the diminished pressure on the heart walls and their consequent dilatation.* This fact may be made plain as follows:

The external air presses against the interior of the lungs with a pressure equal to that exerted on the same area by a column of mercury 760 millimetres high, it distends them and pushes them against the inside of the chest walls, the heart, and great blood-vessels and contents of the thorax. The pressure thus exerted is not equal to that of the external air, since some of the total air pressure on the inside of the lungs is used up in overcoming their elasticity (equal to six millimetres of mercury), and it is only the residue, equal to a column of mercury 754 millimetres high, which pushes the lungs against the heart and great vessels. The actual pressure then on the heart walls, normally, is equal to 754 millimetres of mercury.

How is this pressure changed at an altitude, say of 10,000 feet? The total pressure of the air at that altitude would be equal to a column of mercury 501 millimetres high. The pressure, then, upon the lungs and whole body would be lessened. But, as the person is breathing the same air as that around him, the respiratory act would be unchanged. Prof. Martin and the author found that neither the frequency nor depth of the respiratory act were changed in an animal placed in a rarefied atmosphere. There would be (as, again, we found) a slight fall in blood pressure, which would be very temporary, for the circulation being a system of closed tubes, is but little, if any, affected, and the pressure rises at once to the normal, owing to increased vasomotor action. There would be no increase of negative intrathoracic pressure. Finally, the only organ directly affected at moderate altitudes (of course, at very high altitudes, 12,000 to 18,000 feet, the dyspnœa from want of oxygen would be felt), say from 3,000 to 10,000 feet, would be the heart, and for this reason. As we have said, the pressure on the heart usually is equal to 754 millimetres of mercury. At an altitude of 10,000 feet, however, the general pressure being 501 millimetres, the pressure of the heart would be only 495 millimetres of mercury. Now the arterial pressure, and, therefore, the intracardiac pressure would be the same as when the pressure on the heart walls was 754 millimetres. But one result could follow such conditions, and that would be a stretching and dilatation of the heart walls—especially of the right

side—and this is precisely what is found in many of those who go into high altitudes for their health, or for other reasons, and what we found in experiments upon animals. The heart, weak and diseased possibly beforehand, is unable to stand such strain as is put upon its dilated walls, and so we find its contractions weak, intermittent, and irregular—we have the murmurs, the syncope, the dyspnœa, which are often so marked in high altitudes.

Of course, the want of oxygen is a great cause of the dyspnœa in very high altitudes, but we are quite justified, on physiological grounds, in saying that at the altitudes to which persons are ordinarily sent—three, four, six, seven, or even ten thousand feet—the hæmoglobin can take up all the oxygen the system needs.

Finally, then, and speaking purely from an experimental standpoint, I hold that there is danger to the weak and diseased heart, not only in the use of such apparatus as the pneumatic cabinet, but also in high altitudes; in which conclusion I am supported by the clinical experience of Prof. Loomis, and of Dr. Solly, of Colorado Springs.

MEDICAL PROGRESS.

A Chemical Study of Rabic Virus.—Vincent Richards, whose studies of venom are well known, has pointed out in the *The Indian Medical Gazette* of July, 1886, certain analogies between the poisons of snake bite and of rabies. His paper concludes as follows:

Saliva is, as we know, of a mixed character—that is, it is a combination of secretions from the parotid, submaxillary, sublingual, and buccal glands. These secretions differ in their degree of viscidity, and in their chemical composition, and as the flow of saliva from the different glands—especially the parotid and submaxillary—is considerably influenced by circumstances, the mixed saliva must vary from time to time in the proportion of its several constituents.

It contains, amongst other substances, two proteid bodies, viz., globulin and serum-albumen, and it so happens that these are two of the toxic elements in snake-venom; the globulin attacking certain centres of the medulla oblongata, and the albumen producing motor paralysis. Now, bearing in mind this fact and the circumstance that two distinct types of the disease result from the inoculation of rabic virus, is it not possible, nay, very probable, that the distinctive character of the phenomena in each case depends upon, or results from the inoculation of two or more noxious principles differing in proportion one to another, and to the fluid in which they are found? It may possibly be found that virulence of the saliva results merely from an enormous increase in the proportion of these two elements. I do not say that these, what I will call rabic proteids, have an identical physiological action with those of snake-venom proteids. Indeed, in some particulars, they would seem to exercise some unknown antagonistic action on the same nerve-centres. For the purposes of this paper, I suppose that we have at least two toxic elements of a proteid character in the rabic slaver, and I further assume that one is—

Rabic globulin—having an action upon certain centres of the medulla oblongata, especially the respiratory centre with its neighboring convulsive centre, the cardio-inhibitory centre, the centre for reflex excitation of the secretion of the saliva, and the centres for deglutition and vomiting, and destroying the coagulability of the blood.

And the other—

Rabic albumin—having a special action, more particularly on certain centres of the anterior, temporal, and posterior lobes of the cerebrum.

Assuming that these toxic elements may be present in the saliva of the rabid animal in varying proportions—sometimes one and sometimes the other preponderating—the peculiarities of the disease—hydrophobia—are accounted for. Though it is true that my contention is mainly hypothetical, still it has the merit of affording the best solution of an otherwise perplexing and insoluble problem, as to how the inoculation of the rabic virus can be the cause of two distinct series of physiological phenomena. Whether it is as true as it is plausible remains to be proved. In the meantime, I commend my views to the consideration of those experts in physiological chemistry who may have the necessary opportunity of submitting them to experimental test.

Treatment of Pruritus.—A solution of menthol, two to ten grains in the ounce, is said to be a very effectual remedy in the treatment of the troublesome itching which accompanies urticaria, eczema, and pruritus.—*British Medical Journal*, August 28, 1886.

Intraperitoneal Injections in Acute Hemorrhage.—Rütgers records the case of a woman who, as a result of post-partum hemorrhage, was in a state of profound collapse, and whose veins, after ligature, did not swell, so that no indication for the site of an intravenous injection was obtainable.

A solution of sodium chloride 90 grains, sodium hydrate 5 grains, and distilled water 34 fluidounces, was accordingly introduced into the abdominal cavity by means of a trocar. After three days, during which abdominal pain and subnormal temperature obtained, the general condition was excellent.

It is evident, from this experience, that the absence of swelling in veins after ligature is no sure sign of actual death, and it is suggested that the method described may replace that of hypodermatic injection of water in Asiatic cholera.—*Centralb. f. d. med. Wiss.*, Aug. 7, 1886.

The Treatment of Arterio-venous Aneurism.—A long paper on arterio-venous aneurism communicated by Dr. F. Bramann, of Berlin, to the Fourteenth Congress of the German Society of Surgery, concludes with a comparison of the results of different methods of treatment. The tables of 159 cases collected from different sources show, the author states, that digital compression and other bloodless methods, though occasionally successful in the treatment of arterio-venous aneurism, have not been attended, on the whole, with satisfactory results. Digital compression is very uncertain in its effects, and, to be practised with any chance of success, demands much patience and endurance on the part of both patient and surgeon. It must, therefore, stand below operative methods, by which it is far surpassed with regard both to certainty and

rapidity of the curative results. As a preparatory and auxiliary means of treatment, however, digital compression cannot be too highly recommended; since by it the collateral circulation may be established, and serious circulatory disturbances on the subsequent application of the ligature be thus prevented. Reference is made to cases in which, after a first compression of the carotid artery, lasting one or two minutes, had caused vertigo and syncope, the tendency to such attacks was gradually removed by frequent repetition of the treatment, and consequent dilatation of the collateral channels.

In the operative treatment of arterio-venous aneurism, Hunter's operation is to be rejected. The most promising method is ligature of the vessels above and below the lesion with total or partial extirpation, or, in some cases, with simple division of the sac. It is necessary in most cases to lay open the sac, in order that the opening of any lateral branch in the region of the vascular communication and between the ligatures may not be overlooked. In every case of recent wound of a large artery with its vein, in which the nature of the injury is manifested by free bleeding, a characteristic murmur, and alterations of the pulse, the vessels should be tied at once above and below the seat of injury and divided between the ligatures, and at the same time the wounded portions of artery and vein should be cut away. In cases in which the wound has healed and an arterio-venous aneurism been fully developed, an attempt may be made, though not for long, to treat the lesion by continuous or intermittent digital compression. If this fail, ligature of the vessels above and below the seat of injury is to be recommended, together with complete extirpation of the sac when this is small and circumscribed, and either partial extirpation or simple incision, followed by plugging, in case of a very large sac or of one with ill-defined wall.

The only contraindication of operative treatment is extreme general disease of the vessels, especially advanced arterial sclerosis. Long duration of the aneurism does not in itself contraindicate such treatment. A case has been recorded of successful treatment by operation of an arterio-venous aneurism in front of the elbow, that had lasted for twenty-five years, and another of a like aneurism of the femoral of twelve years' standing. With regard to the dilatation of the veins in the affected limb, this always diminishes considerably in size after the operation, and may even disappear altogether. Occasionally, however, after the patient has recovered and taken to active muscular exercise, circulation is reëstablished in these veins, and dilatation is again observed. This venous dilatation, however, Dr. Bramann states, does not attain so high a degree as to interfere with the functional activity of the limb.—*London Medical Record*, July 15, 1886.

Treatment of Hydrophobia in Poland.—A Polish physician, Prince Ignace Jagell, has been occupied since 1858 in the study of hydrophobia, and in a recent letter to the French Academy combats the methods and conclusions of Pasteur. Prince Jagell states that he has treated, in the course of his life, eighty-eight individuals bitten by mad dogs and wolves, and that all were cured by the internal administration of an infusion of the bark of the *Spiræa filipendula*. Twenty-eight of the patients were already in the first period of hydrophobia when the treatment was begun.

Several German journals have commended the same drug as a prophylactic in the disorder under consideration.—*Rev. de Thérapeutique*, August 15, 1886.

Refractive Character of the Eyes of Mammalia.—In the course of an elaborate article with this title in *The Royal London Ophthalmic Hospital Reports* for July, 1886, Drs. Lang and Barrett write as follows:

"The usual form of an astigmatic eye—a vertically flattened sphere—is the shape that a soft ill-supported sphere would assume by reason of its own weight. When such a sphere is acted upon by four muscles vertically and by only two horizontally, leaving aside any influence the lids may exert, it is readily conceivable that a weakly formed sclerotic and cornea should assume the astigmatic shape. Once formed, this shape would have a tendency to be inherited, especially in domestic animals, amongst whom the law of the survival of the fittest does not obtain, at least as regards the eyes. In albino rabbits, which do not admit of much crossing, this defect was always marked, the astigmatism in our cases averaging 1.275 D.

"On only one point, however, is the evidence decided and convincing; the principal meridians of the astigmatic eye are always in the direction of and at right angles to the direction of the long axis of the pupil, to this extent only does this evidence justify the consideration of the matter from a teleological standpoint. Were the slit-like pupil developed to obviate the evil results of the astigmatism, we should expect to find that the meridian of least curvature in myopic, and of greatest curvature in hypermetropic eyes, corresponded in direction with the long axis of the pupil. One would also certainly expect that animals with round pupils should not possess very astigmatic eyes. Yet every one of these requirements is unsatisfied, and we find throughout that the optical construction of these eyes evinces the existence of some general developmental agency which pays little regard to the *existing* shape of the pupil.

"We feel that we are quite unable in the present state of our knowledge to conjecture the mode of origin, or even the possible purpose of this slit-like pupil, but we think that the evidence adduced indicates the probability of that explanation being obtained from a developmental and not from a teleological standpoint."

Sudden Death from a Blow on the Testicles.—At a recent meeting of the Varna Medical Society, Dr. Ivanoff recorded the following rare case (Bulgarian *Meditzinsko Spisanïe*, June 20, 1886, p. 440). A man, aged between forty-five and fifty years, fought with a woman on the street. During the fight the woman dealt a violent blow on his genital organs. The man shouted, 'I am dying!' staggered, and fell insensible. The author, who was almost immediately fetched to the spot by a policeman, found the patient lying on his back, motionless, pulseless, and breathless; his face, neck, and scrotum being very red. Not a trace of ecchymosis or any other sign of injury was detected anywhere in the man. Since there seemed to be heard a slight cardiac murmur, and a slight tremor to be felt in the carotids, Dr. Ivanoff without any delay resorted to

artificial respiration. But neither forty-five minutes' manipulations nor electrization could establish the man's breathing. The congested parts soon became livid, and every sign of life extinct. At the *post-mortem* examination, there were found only intense congestion of the meninges and brain, congestion of the lungs with numerous punctiform ecchymoses, accumulation of dark red fluid blood in the cardiac cavities, congestion of the stomach, liver, kidneys, and testicles. Everything else was quite normal. Basing this conclusion on all the facts as sketched above, the author stated (forensically) that death followed from syncope, which had been brought about by sudden violent pain caused by a blow on the testicles.—*London Medical Record*, August 16, 1886.

Researches on Myohæmatin and the Histohæmatins.—Dr. C. A. MacMunn (*Proc. Roy. Soc.*, 1886, 240) has found that the organs and tissues of invertebrate and vertebrate animals, from echinoderms to man, present a series of spectra which are all evidently connected with each other. In general the spectra may be said to consist of three bands—one before D, one or two between D and E, and sometimes one or two others nearer violet. The pigments to which these spectra are due are called histohæmatins, and occur in an oxidized and deoxidized condition. In all animals which possess striped muscle there is to be found in their tissue a yellow or reddish-yellow pigment—myohæmatin—distinguished by the sharpness and narrowness of its bands. Three bands are always present—one between C and D, close to D, which corresponds to the first band of the histohæmatins spectrum; two very narrow and sharp bands between D and E, and one or two nearer violet, not constantly present. Dr. MacMunn concluces that these pigments are concerned in the internal respiration of the tissues and organs in which they are found. Hæmochromogen has been found by the same indefatigable observer in the suprarenal capsules of several animals. This pigment would appear to be here, as in other places—*e. g.*, the bile—excretory. Hence one of the functions of the suprarenal capsules is to cause a downward metamorphosis of hæmoglobin and the histohæmatins. If from disease this metabolism is prevented, the incompletely metabolized pigments circulate in the blood, and staining of the skin and mucous membrane, as in Addison's disease, may take place. Dr. MacMunn has found in the urine of Addison's disease such an imperfect metabolit.—*Dublin Journal of Medical Science*, Sept. 1886.

Potassium Permanganate in Burns and Frost-bite.—In the *Meditzinsko Obozrenïë*, 1886, No. 8, p. 758, Dr. A. A. Züboff writes that, having tried permanganate of potassium in forty-four cases of burns and thirteen cases of frost-bite, he arrived at the following conclusions: 1. Permanganate of potassium, in the shape of frequently changed compresses (linen or hygroscopic cotton-wool soaked in a solution of one or two grains to an ounce of water) is an effective remedy for frost-bite of the first and second degrees. 2. The same lotion acts as successfully in burns of the first degree. 3. It is less successful in burns of the second degree. At all events, the permanganate lotion rapidly relieves inflammation around blisters, and pain, and prevents suppuration when blisters remain intact. In this category of cases, it is advisable to employ a weaker solution (half a grain, or even less, to an ounce). Two cases are given in detail. One of the patients received (when taking a vapor-bath) a scald of the first degree, extending from the breasts to the inguinal folds anteriorly, and between the same levels posteriorly. Pain disappeared within an hour after the application of the permanganate lotion. Soon the epidermis began to peel off. She left, well, in eleven days. Another woman had a similar scald of the face and a hand. She also obtained rapid relief, the treatment lasting a week.—*London Medical Record*, August 16, 1886.

The Treatment of Pericarditis.—Professor Nothnagel, of Vienna, in a clinical lecture on the treatment of pericarditis, advises that in cases where there is pain in the cardiac region, fever, and the commencement of exudation, leeches varying in number from three to ten, according to the gravity of the symptoms and the constitution and strength of the patient, should be applied. The leeches should be renewed every four or six days. Cupping may be substituted, but leeches are preferable. An ice-bag should be applied, or a directing apparatus through which cold water can be constantly supplied to the part. Cold compresses are of no use unless they are laid on ice, and then they must be changed every five minutes. Digitalis for internal use is indicated under certain circumstances. It is useful if the cardiac action is greatly increased, especially if there are signs of the heart muscle becoming implicated, when it should be given in somewhat larger doses. Digitalis is not desirable in the earlier stages of the disease, but in the later ones, when there are signs of weakness of the heart muscle and the pulse is weak, it is indispensable. Other internal remedies are useless. Mercurialization—viz., calomel in small doses of three-quarters of a grain internally, and gray ointment externally—has no effect. The pain is scarcely ever severe, and if it is persistent it may be relieved by cold and bloodletting. To this a high temperature is no drawback, as the fever subsides as the inflammatory appearances disappear. If effusion has begun, other means must be used—such as counter-irritation of the skin and the promotion of reabsorption. Ice and bloodletting are of no use in this case. The cardiac region must be painted with equal parts of gall and iodine tincture, or an ordinary cantharides plaster may be applied, which should be kept on from eight to twelve hours—till a blister is raised. This is of greater use in subacute than in acute pericarditis. Digitalis does not promote reabsorption directly, but indirectly by its influence on the action of the heart. Should the patient's life be threatened by copious effusion, paracentesis of the pericardium must be performed. This operation is often employed, and with not unfavorable results. Great care must be observed; the pointed trocar of Dieulafoy's apparatus must not be used, but a blunt one like that of Dr. Fraentzel.—*The Lancet*, September 4, 1886.

The Therapeutic Action of Chloride of Sodium.—After dealing with the physical and chemical properties of this salt, and its physiological action on

animals and plants, DR. BRANCHE gives the results of his own observations in man. The blood, the saliva, and the urine show a notable increase in the proportion of the salt a few minutes after its ingestion. Its effect on digestion is not only to augment the secretion of gastric juice, but also to increase its acidity. After taking ten grammes daily, more than the usual quantity, for two months, the number of blood corpuscles was found to have increased, with a diminution of the albumen and watery constituents of the blood. The excretion of urea is increased, owing either to better diffusion or to acceleration of organic combustion. With ten grammes daily in addition to the ordinary consumption of salt, the amount of urea was augmented to the extent of four grammes (Rabuteau). Although certain advantages appear to follow a slight increase in the quantity of salt taken, an excess is certainly injurious; in one case death followed the ingestion of 500 grammes of sea salt. This toxic effect, however, has been denied. Deprivation of the ordinary ration of salt is rapidly followed by general feebleness, albuminuria, and anæmia. The condition likely to derive most benefit from a course of treatment with chloride of sodium is (according to Dr. Branche) struma, but anæmia and tuberculosis are also improved, if not cured. Dr. Pidoux recommends phthisical patients to eat largely of salt at meals. Goat's milk, rendered saline by the addition of twelve to fifty grammes of salt to the diet of the animal daily, is highly spoken of. Bouchardat has remarked that well-salted meat diminishes the thirst of diabetic patients to some extent, and lessens the excretion of sugar. In the form of baths its good results are well known in the treatment of chronic rheumatism, gout, gravel, and biliary calculi. Several observers have seen malarial fever arrested by doses of salt varying from ten to fifteen grammes. In solution, it has been recommended for intravenous injection for cholera, and to destroy the *oxyuris vermicularis* in children. The effect of salt is antidotal to nux vomica and curare, and to lead and silver salts. The necessity for avoiding the ingestion of salt in any form for some hours after the administration of calomel is, or should be, well known. In conclusion, Dr. Branche points out the benefit to be derived from the use of mineral waters of the Friederichshall type, containing chloride of sodium, whereby the depressing effects of saline laxatives is counteracted by the salt.—*London Medical Record*, July 15, 1886.

MYDRIATICS IN OPHTHALMOLOGY.—In a lecture thus entitled, which is published in the *Twenty-Second Annual Report of the Alumni Association of the Philadelphia College of Pharmacy for 1886*, DR. S. D. RISLEY presented the following conclusions:

1. That the sulphates of atropine, duboisine, and hyoscyamine, and the hydrobromate of homatropine, are efficient agents for paralyzing the accommodative function, and in the treatment of asthenopic eyes.

2. That in the employment of the last three named the duration of the treatment is very much shortened.

3. That, for the correction of anomalies of refraction in otherwise normal eyes, the homatropine is to be preferred.

4. That if retino-choroidal disturbance is also present, hyoscyamine or duboisine is preferable: (*a*) to atropine, because of the shorter duration of the treatment; (*b*) to homatropine, because of their more persistent control over the ciliary muscle.

5. That hyoscyamine is preferable to duboisine, since the tendency to systemic poisoning is less.

The preparations of hyoscyamine which have of late been furnished me, have seemed more persistent in their control of the accommodation than those first employed. In a few instances this has been so markedly the case as to justify the suspicion that atropine had been used to substitute or adulterate the hyoscyamine, or that some other alkaloid was present in the hyoscyamus, which, in the process of manufacture employed by some chemists, was not eliminated from the hyoscyamine.

INFANT FEEDING.—DR. E. P. THURSTAN writes as follows to *The Lancet* of Sept. 4, 1886. The vendors of the various foods for infants lay great stress on the fact that the starch of the wheat has undergone some change which renders it easier for digestion. This may be true to some extent; the diastase, when present, may convert a portion of the starch, but this (in the early weeks of life, at all events) is probably a secondary function. The following case which has recently occurred in my practice will illustrate my views, and, I think, confirm their correctness:

The wife of a well-to-do tradesman was prematurely confined of a female child nine weeks before she was expecting it; the presentation was breech and footling. When the child was born, it was cyanosed and made no attempt to breathe. After performing artificial respiration for five minutes the breathing became fairly established; but the child was still cyanosed, and did not cry. I cut the cord and bled the child to two drachms, after which it cried fairly strongly. The mother had never been able to nurse her children, and no attempt to do so was made now. It was fed on milk and water, half and half of each. The weather being hot, we had no difficulty in keep up the warmth of the child, and for a few days all went well, except that the child could not be induced to drink more than half a pint of milk daily. Three days after birth it weighed 3 lb. 8 oz. A week later it weighed 3 lb. 9½ oz. In the meantime the cord and surrounding rag had come away, so that the actual gain could not have been more than an ounce, probably less. Shortly after this, sickness and slight diarrhœa came on. Veal-tea was ordered with the milk, and cream and water twice a day, instead of entire milk and water. Some powders were given, containing a third of a grain of mercury and chalk, with a little aromatic confection, ipecacuanha, and rhubarb. The diarrhœa and sickness abated, but the child was still taking very little. Eight to ten drops of brandy were added to the milk three times daily. At the end of another week the weight was 3 lb. 10 oz., being a gain of only ½ oz. The child was now fed on milk, thickened with a little patent farinaceous food. The following week the weight was 4 lb., the gain being 4 oz. The week after, the weight was 4 lb. 9½ oz., being a gain of 9½ oz. The child is now doing well.

Here is surely a clear case of a life preserved by a change of diet, and a change, too, from a diet which I may call orthodox to one that is often spoken of as absolutely injurious.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 18, 1886.

OPERATION FOR MALIGNANT DISEASE IN THE THROAT.

THE subject of the treatment of malignant disease in the throat has attracted much attention during the past few years, and in this country became of peculiar interest a short time ago on account of the sufferings and death of General Grant. On March 21, 1883, we gave an editorial *résumé* of the facts and opinions then accessible in regard to it. But the subject is of sufficient importance to justify our recurring to it, especially as a number of valuable contributions to its literature have recently appeared.
